Table 17 Recommended heat-treating practices for carbon-tungsten special-purpose tool steels

Steel	Normalizing temperature[(a)]		Annealing					Hardening						
								Temperature				Holding time, min	Quenching medium	Quenching hardness, HRC[(d)]
			Temperature[(b)]		Cooling rate[(c)]		Annealed hardness, HB	Preheat		Austenitizing				
	°C	°F	°C	°F	°C/h	°F/h		°C	°F	°C	°F			

F1	900	1650	760-800	1400-1475	22	40	183-207	650	1200	790-870	1450-1600	15	W, B	**64**
F2	900	1650	790-815	1450-1500	22	40	207-235	650	1200	790-870	1450-1600	15	W, B	**66**
F3	**900**	**1650**	**790-815**	**1450-1500**	**22**	**40**	**212-248**	**650**	**1200**	**790-870**	**1450-1600**	**15**	**W, B, O**	**66**

W, water: B, brine; O, oil.

(a) Holding time, after uniform through heating, varies from about 15 min, for small sections, to about 1 h, for large sections. Work is cooled from temperature in still air.

(b) Lower limit of range should be used for small sections, upper limit for large sections. Holding time varies from about 1 h, for light sections and small furnace charges, to about 4 h, for heavy sections and large charges; for pack annealing, hold for 1 h per inch of pack cross section.

(c) Maximum cooling rate. Rate is not critical after steel has been cooled to below 540 °C (1000 °F).

(d) Typical average hardness values; subject to variations depending on austenitizing temperature and quenching medium employed

As a group, these steels are shallow hardening and usually are quenched in water or brine. Steel F3, because of the chromium addition, is the highest in hardenability.

Normalizing and Annealing. These steels should be normalized after they have been forged or otherwise subjected to temperatures above their hardening temperatures. Normalizing and annealing practices are essentially the same as those recommended in the preceding section (see "Low-Alloy Special-Purpose Steels") of this article. Recommendations for normalizing and annealing the F steels are given in Table 17.

Stress relieving as outlined previously for the low-alloy special-purpose steels may be advantageously applied also to the F steels. The same procedure as that described for the L steels would be used.

Austenitizing. Preheating and austenitizing temperatures recommended for the carbon-tungsten special-purpose tool steels are given in Table 17. Equipment and practices are generally the same as those previously described for the low-alloy special-purpose steels.

Quenching. Water or brine quenching causes high distortion in parts made of the F steels. This is often used to advantage in the rehardening of worn dies that have been used for cold drawing of bars and tubes. Such dies are flush quenched--that is, a spout of water is directed into the bore, thus causing shrinkage and allowing further use of dies for the same product size.

Tempering. Because tools made of the F steels (cold drawing dies, for example) are used mainly for applications requiring wear resistance, they are usually placed in service at or near their maximum hardness. Therefore, tempering temperatures higher than 205 °C (400 °F) are seldom used. The effect of tempering temperature on hardness for the F steels is shown in Fig. 22.

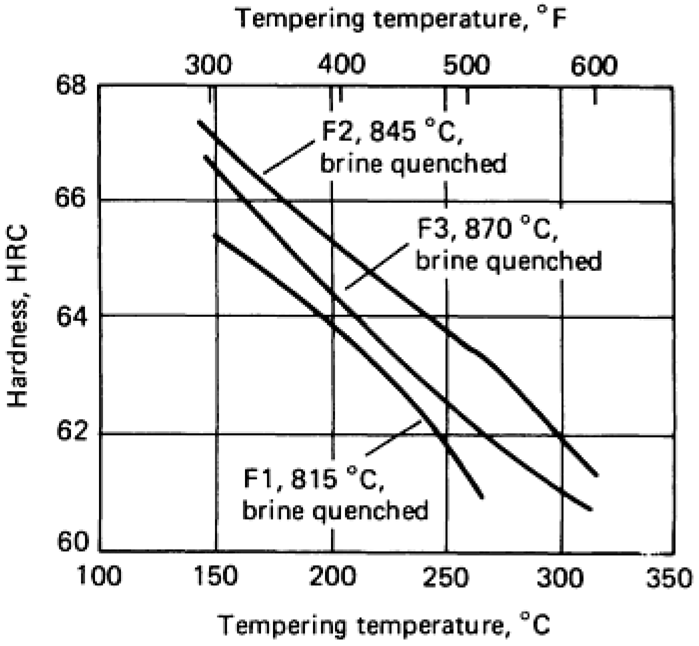

Fig. 22 Tempering characteristics of carbon-tungsten special-purpose tool steels tempered 2 h after being brine quenched

Mold Steels

The principal use of these type P steels is for plastic molds. However, some steels, such as P4, P20, and P21, are used also for die-casting dies. The several types vary widely in composition (see Table 1 of the article "Introduction to Heat Treating of Tool Steels"), from the unalloyed hubbing iron P1, to P4, P6, and P21, which contain over 5% total alloying elements.

The wide variations in composition, method of forming the mold cavity, molding method, and material to be molded are major influences on choice of mold material as well as method of heat treating. The two most common methods of heat treating the mold steels are (1) preharden the steel (or partially machined mold or die) to about 30 to 36 HRC, finish machine, and use at this hardness level and (2) case harden by carburizing. Nitrided molds have proved successful in some instances, but nitriding is not used extensively.

When molds are carburized or nitrided, the same procedures are used as for production steels.

Heat-treating practices for the mold steels are summarized in Table 18. P21 is a special type of mold steel that is heat treated by the manufacturer and delivered ready for the user to machine and place in operation without further treatment. As noted in Table 18, this steel is hardened by solution treating and aging.

Table 18 Recommended heat-treating practices for mold steels

Steel	Normalizing temperature[(a)],		Annealing					Carburizing temperature		Hardening (after carburizing)				
			Temperature[(b)]		Cooling rate[(c)]		Annealed hardness, HB			Austenizing temperature		Holding time, min	Quenching medium	Quenched hardness, HRC
	°C	°F	°C	°F	°C/h	°F/h		°C	°F	°C	°F			
P1	Not req		730-900	1350-1650	22	40	81-101	900-925	1650-1700	790-800	1450-1470	15	W, B	**62-64**
P2	Not req		730-815	1350-1500	22	40	103-123	900-925	1650-1700	830-845	1530-1550	15	O	**62-65**
P3	Not req		730-815	1350-1500	22	40	109-137	900-925	1650-1700	800-830	1470-1530	15	O	**62-64**
P4	Not req		870-900	1600-1650	14	25	116-128	970-995	1780-1820	970-995	1780-1820	15	A	**62-65**
P5	Not req		845-870	1550-1600	22	40	105-116	900-925	1650-1700	845-870	1550-1600	15	O, W	**62-65**
P6	Not req		845	1550	8	15	183-217	900-925	1650-1700	790-8815	1450-1500	15	A, O	**60-62**
P20	900	1650	760-790	1400-1450	22	40	149-179	870-900[(d)]	1600-1650[(d)]	815-870	1500-1600	15	O	**58-64**
P21	**900**	**1650**	**Not rec**		**Hardened by solution treating and aging[(e)]**									

W, water; B, brine; O, oil; A, air; Not rec, not recommended; Not req, not required;

(a) Holding time, after uniform through heating, varies from about 15 min, for small sections, to about 1 h, for large sections. Work is cooled from temperature in still air.

(b) Lower limit of range should be used for small sections, upper limit for large sections. Holding time varies from about 1 h, for light sections and small furnace charges, to about 4 h, for heavy sections and

large charges; for pack annealing, hold for 1 h per inch of pack cross section.

(c) Maximum. Rate is not critical after cooling to below 540 °C (1000 °F).

(d) When applicable.

(e) Solution treatment: Hold at 705 to 730 °C (1300 to 1350 °F) for 1 to 3 h, quench in air or oil; approximate solution treated hardness, 24 to 28 HRC. Aging treatment: Reheat to 510 to 550 °C (950 to 1025 °F); approximate aged hardness, 40 to 30 HRC

Annealing temperatures and expected resulting hardness values are indicated in Table 18. For some types, such as P1, the annealing temperature is not critical. A more important factor is surface protection, especially if the mold cavities will be formed by hubbing. If surfaces are allowed to carburize, even slightly, during annealing, subsequent rubbing will be impaired.

Usually, parts are packed in an inert material such as spent pitch coke and are held at annealing temperature only long enough to become heated through; they are then cooled in the pack to below 540 °C (1000 °F), after which they may be removed from the pack. If rubbing is to follow, it is usually preferable to use the lower side of the annealing temperature range to minimize the danger of carburizing, even though annealing at the higher side of the range will result in slightly lower hardness. Atmosphere-controlled furnaces that can be programmed for slow cooling can also be used for annealing. For hubbing deep cavities, two or more in-process anneals are sometimes required.

When cavities will be formed entirely by machining (sometimes a combination of hubbing and machining is used), annealing usually is neither necessary nor desirable, because slightly harder structures can be machined more easily. Steels as received from the manufacturer are usually suitable for machining. If hardened molds require reworking, they can be annealed as recommended in Table 18.

Additional Heat Treatments. Variations in heat treatment, as necessitated by differences in composition, properties, and intended use, are discussed in the following sections for steels P1 to P20.

P1 steel, although shown in Table 1 of the article entitled "Introduction to Heat Treating of Tool Steels" as containing no alloying elements, may contain about 0.10% V, which promotes a finer grain after carburizing, with no apparent sacrifice in hubbability. This steel usually is used only for hubbed molds for injection molding of general-purpose plastics.

P1 steel can be carburized by any of the regular practices. Whether the steel is reheated to the austenitizing temperature or quenched from a programmed furnace depends on equipment used. Full hardness (Table 18) can be achieved only by water or brine quenching. Practice varies as to working hardness range.

A minimum tempering temperature of 175 °C (350 °F) is recommended. This will retain a finished surface hardness of 60 HRC or slightly higher. However, a more commonly desired hardness range is 54 to 58 HRC, which is obtained by tempering at 260 to 315 °C (500 to 600 °F). If the distortion encountered from water quenching cannot be tolerated for a particular mold design, a type of mold steel that can be hardened by oil quenching must be used instead of P1.

P2 steel also is a hubbing steel, although it is less easily hubbed than P1. Carburizing and hardening practice and the working hardness range are the same as for P1, except that the alloy content of P2 increases hardenability so that full hardness can usually be obtained by oil quenching, thus minimizing distortion.

P3 steel is also hubbed, but it is less easily hubbed than P1 or P2. Except that P3 is usually oil quenched, the carburizing and hardening practice for it is essentially the same as that outlined above for P1. The operating hardness range may vary from 54 to 64 HRC, but common practice is to temper at about 315 °C (600 °F) to achieve a final hardness of 54 to 58 HRC.

P4 steel is sometimes used hubbed, but because of its resistance to cold deformation it is more often used for machined molds or dies. Of all the steels in this group, P4 is the most resistant to wear and to softening by tempering. Because of these properties, it is commonly used for injection molding of plastics that require high curing temperatures and for dies used for die casting low-melting alloys. For the latter application, a common practice is to carburize P4 in cast iron chips to obtain a slight increase in carbon content at the surface. The effect of carburizing practice, as well as case and core hardness values after tempering, is shown in Fig. 23.

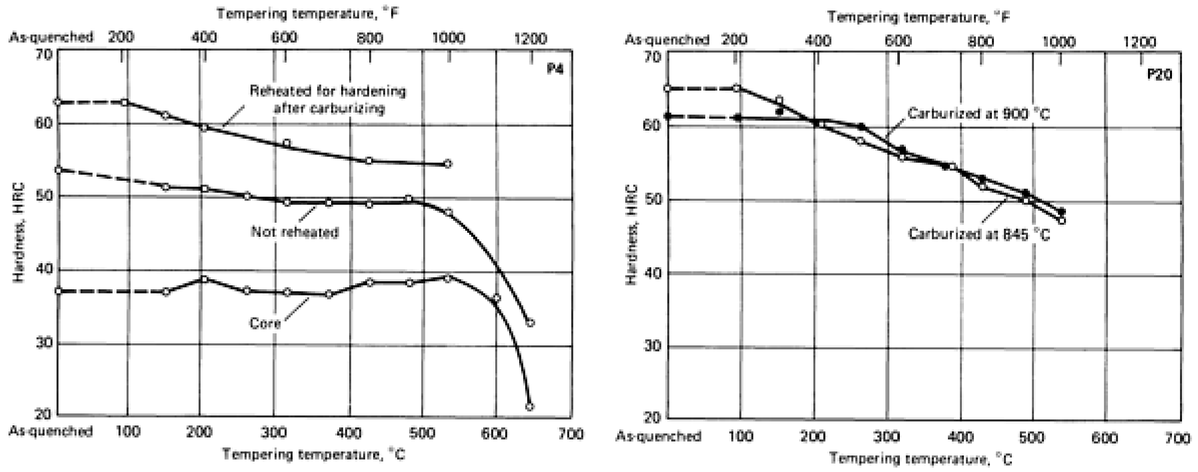

Fig. 23 Tempering characteristics of carburized mold steels. (a) Upper curve represents steel carburized in hardwood charcoal 915 to 925 °C (1675 to 1700 °F) for 8 h, air cooled in pack, reheated at 940 to 955 °C (1725 to 1750 °F), cooled in air and tempered. Middle curve represents steel carburized in cast iron chips at 940 to 955 °C (1725 to 1750 °F), removed from pack, cooled in air and tempered. (b) Surface hardness after heating at temperature for 2 h in carburizing compound, oil quenching, and tempering

Because of its high alloy content, P4 steel can be hardened by air cooling. However, it is sometimes quenched in oil to minimize scaling during cooling. For use in plastic molds, the most common working range is 56 to 60 HRC, which may be obtained by tempering the carburized and hardened molds at 205 to 315 °C (400 to 600 °F) (see Fig. 23).

P5 steel, in which chromium is the major alloying element, approaches P1 in ease of hubbing and has a core strength equivalent to that of P3. After carburizing, a surface hardness of 65 HRC can be achieved by water quenching, or slightly lower values by oil quenching. Choice of quenching medium depends on mold configuration, allowable distortion, and required hardness. A common working range is 54 to 58 HRC; this can be obtained by tempering at about 260 °C (500 °F).

P6 steel, because it can seldom be annealed to a hardness of less than 183 HB (Table 18), is difficult to hub, and hence it is usually used for machine-cut cavities. It can be carburized by conventional practice. Because of its hardenability, heavy sections of P6 can be oil quenched to full hardness from 790 to 815 °C (1450 to 1500 °F). The as-quenched surface hardness is not quite so high as for some other types, because the high nickel content of P6 promotes retention of austenite. Some of this retained austenite is transformed in tempering, with the result that after tempering up to about 260 °C (500 °F) the hardness will be little or no lower than that obtained after quenching. By tempering at 315 °C (600 °F), the most common working hardness range (54 to 58 HRC) is obtained. In some plants, a working hardness range of 58 to 61 HRC, obtained by tempering at 260 °C (500 °F), is considered preferable.

P20 steel is a popular mold material for either injection or compression molding, and also for die casting low-melting alloys.

For injection molding of the general-purpose plastics or die casting of low-melting alloys, P20 is usually used in the prehardened condition. It is available at hardness levels of about 300 HB or slightly higher. In this condition, cavities are machined and the dies or molds placed in service without further heat treatment. Annealed molds or dies can be austenitized at 845 to 870 °C (1550 to 1600 °F), oil quenched, and tempered at 540 °C (1000 °F), to obtain a hardness of about 300 HB.

Type P20 is often carburized for molds used in compression molding, particularly for molding the more abrasive plastics. Carburizing temperatures no higher than 900 °C (1650 °F) are recommended for this steel, because higher temperatures may impair polishability; otherwise, conventional carburizing practice is used, and molds may be quenched in oil directly from the carburizing temperature. A common working range is 54 to 58 HRC.

Tempering characteristics for P20 carburized at two different temperatures are given in Fig. 23.

This steel is sometimes nitrided for special applications. Conventional nitriding practice is employed. Before being nitrided, P20 should first be quenched and tempered to about 300 HB as outlined above, and cavities should be machined; following this sequence will ensure freedom from carburization or decarburization.

Control of Distortion in Tool Steels

Revised by Bruce A. Becherer, Teledyne Vasco; and Larry Ryan, Lindberg Heat Treating Company

Introduction

DIMENSIONAL CHANGES in tool steel caused by heat treatment are particularly important to the manufacture, proper design, and use of tooling. Although no simple solution to the problem of distortion exists, an understanding of the complex factors involved will lead to procedures for minimizing the amount of change in dimensions. This article deals primarily with irreversible changes that affect the actual net dimensional change or distortion of a part. The reversible effects of thermal expansion and contraction--when a part is heated from room temperature to austenitizing temperature and cooled to room temperature--tend to cancel each other out. Reversible changes cause stressing in the elastic range. Under such conditions, the initial dimensional values can be restored by a return to the original state of stress or temperature.

The upper limit of reversible dimensional change in a tool steel is determined by the stress required to initiate deformation (that is, the elastic limit corresponding to a preselected value of plastic strain), the elastic deformation per unit stress (modulus of elasticity), the effect of temperature on these properties, the coefficient of thermal expansion, and the temperature-time combinations at which stress relief and phase changes occur.

For practical purposes, the modulus of elasticity of all tool steels, regardless of composition or heat treatment, is 210 GPa (30×10^6 psi) at room temperature. Therefore, if a tool steel part deforms excessively under service loading but returns to its original dimensions when the load is removed, a change in grade or type of tool steel or in heat treatment will not be useful. To counteract excessive elastic distortion it is necessary to reduce the applied stress by increasing the section size, or to use a tool material with a higher modulus of elasticity (such as cemented tungsten carbide).

Irreversible changes in size or shape of tool steel parts are those caused by stresses that exceed the elastic limit or by changes in metallurgical structure (most notably, phase changes). Such irreversible changes sometimes can be corrected by thermal processing (annealing, tempering, or cold treating) or by mechanical processing to remove excess material or to redistribute residual stresses.

Nature and Causes of Distortion

Distortion is a general term encompassing all irreversible dimensional changes. There are two main types: size distortion, which involves expansion or contraction in volume or linear dimensions without changes in geometrical form; and shape distortion, which entails changes in curvature or angular relations, as in twisting, bending, and/or nonsymmetrical changes in dimensions. Frequently, both size and shape distortion (shown in Fig. 1) occur during a heat-treating operation.

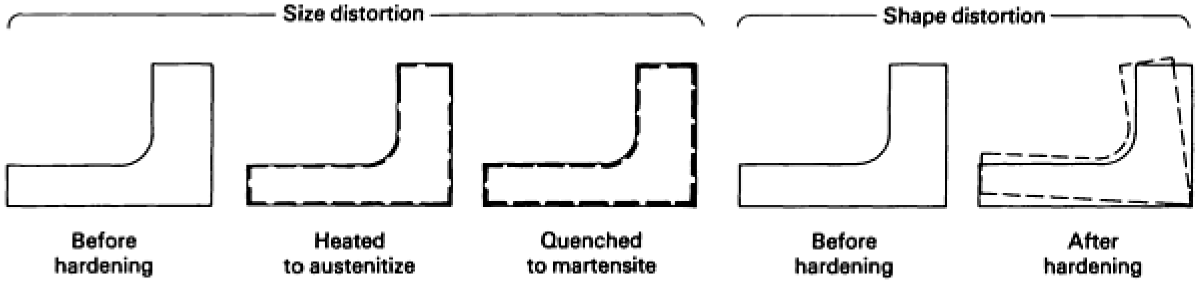

Fig. 1 Size and shape distortion in hardening

Size distortion is the result of a change in volume produced by a change in metallurgical structure during heat treatment. Shape distortion results from either residual or applied stresses. Residual stresses developed during heat treatment are caused by thermal gradients within the metal (producing differing amounts of expansion or contraction), by nonuniform changes in metallurgical structure, and by nonuniformity in the composition of the metal itself, such as that caused by segregation.

Changes in metallurgical structure during heat treatment of tool steels are produced by the three steps described below.

The first step involves heating an annealed structure (usually consisting of ferrite and spheroidal carbides, commonly called spheroidite) to about 800 °C (1450 °F) or higher to change the ferrite to austenite and to dissolve all or most of the spheroidal carbides to the austenite. For plain carbon or low-alloy tool steels, austenitizing results in a contraction in volume. The extent of volumetric contraction decreases with increasing amounts of carbon present in the composition. This can be approximated as follows:

$$V_{SA} = -4.64 + 2.21\ (\%\ C) \qquad \textbf{(Eq 1)}$$

where V_{SA} is the volume change in percent that occurs when spheroidite transforms to austenite. By use of this equation, it can be estimated that, if heated to a temperature high enough to dissolve all of the carbon in the austenite, a 0.50% carbon tool steel would exhibit a volume change of -3.53%, a common type containing 1% carbon would exhibit a change of -2.43%, and a very high-carbon type containing 1.5% carbon would exhibit a change of -1.33%. However, tool steels having carbon contents higher than that of the eutectoid composition are normally austenitized at temperatures only high enough to dissolve the eutectoid amount of carbon. Under these circumstances, 1% carbon and 1.5% carbon tool steels would exhibit changes in volume of -2.77 and -2.53%, respectively, after austenitizing. These percentages are less than that calculated directly from Eq 1 because an allowance must be made for the volume occupied by undissolved carbides, which is about 3.5% for the 1.0% carbon steel and about 12% for the 1.5% carbon steel.

The second step involves cooling quickly enough to cause the austenite to transform to martensite. The steel expands on transformation, the amount of expansion being in inverse proportion to the amount of carbon in solution in the austenite:

$$V_{AM} = 4.64 - 0.53\ (\%\ C) \qquad \textbf{(Eq 2)}$$

where V_{AM} is the percent volume change that occurs when austenite transforms to martensite. By use of Eq 2, it can be estimated that a 0.5% carbon tool steel would exhibit a volume increase for this transformation of 4.37%, and that 1.0 and 1.5% carbon steels would exhibit increases of 4.07% and 3.71%, respectively, if austenitized at the normal austenitizing temperature (only 0.8% carbon, the eutectoid amount, in solution, and again allowing for the volume occupied by undissolved carbides).

Equations 1 and 2 can be used to calculate the net change in dimensions in a tool steel when it is heat treated to transform it from an annealed to a fully hardened (martensitic) state. For the examples referred to above, normal heat treatment would produce net volume increases of -3.53 + 4.37 = 0.84% in the 0.5% carbon tool steel, -2.77 + 4.07 = 1.30% in the 1.0% carbon steel, and -2.53 + 3.71 = 1.18% in the 1.5% carbon steel. Net changes in linear dimensions would be about one-third of the corresponding net changes in volume.

The third step involves reheating the freshly formed martensite to relatively low temperatures (tempering) to increase toughness and reduce lattice stress. Tempering produces various changes in metallurgical structure, depending on temperature and time at temperature.

After very long times at room temperature or shorter times at temperatures up to 200 °C (400 °F), the high-carbon martensite in plain carbon and low-alloy tool steels decomposes into low-carbon martensite (about 0.25% carbon) plus epsilon carbide, with an accompanying contraction in volume. At higher tempering temperatures, 200 to 430 °C (400 to 800 °F), the martensite decomposes into ferrite plus cementite.

Transformation of the maximum amount of austenite to martensite on quenching usually requires continuous cooling to below the martensite-finish temperature (M_f), which for a eutectoid tool steel is about -50 °C (-60 °F). To prevent cracking of very large or very intricate pieces, it is common practice to remove the tool from the quenching medium and to begin tempering it while it is still slightly too warm to hold comfortably in the bare hands (about 60 °C, or 140 °F). Under these conditions, a substantial proportion of the structure (10% or more) may still be austenite. Most alloying

elements lower the M_f temperature. Consequently, more austenite is retained at room temperature in the more highly alloyed tool steels. On tempering at increasing temperatures in the range of 120 to 260 °C (250 to 500 °F), increasing amounts of this retained austenite transform to bainite for some tool steel compositions, with an accompanying expansion in volume.

Depending on the alloy content of the tool steel, all, some, or none of the retained austenite will transform during tempering. In some highly alloyed tool steel compositions, cementite redissolves at tempering temperature of 540 to 595 °C (1000 to 1100 °F) to form alloy carbides, which induces an additional expansion in volume. The formation of alloy carbides during tempering is characteristic of tool steels containing large amounts of carbide-forming elements such as chromium, molybdenum, and tungsten, which are found in high-speed tool steels.

Size Distortion in Tool Steels

Typical volume percentages of martensite, retained austenite, and undissolved carbides are given in Table 1 for four different tool steels quenched from their recommended austenitizing temperatures.

Table 1 Microconstituents in various tool steels after hardening

Steel	**Hardening treatment**	**As-quenched hardness, HRC**	**Martensite, vol%**	**Retained austenite, vol%**	Undissolved carbides, vol%
W1	790 °C (1450 °F), 30 min; WQ	67.0	88.5	9	**2.5**
L3	845 °C (1550 °F), 30 min; OQ	66.5	90	7	**3.0**
M2	1225 °C (2235 °F), 6 min; OQ	64	71.5	20	**8.5**
D2	**1040 °C (1900 °F), 30 min; AC**	**62**	**45**	**40**	**15**

Note: WQ, water quench; OQ, oil quench; AC, air cool

Typical changes in linear dimensions for several tool steels are given in Table 2. As shown in this table, some tool steels such as A10 show very little size change when hardened and tempered over the entire range from 150 to 600 °C (300 to 1100 °F).

Table 2 Typical dimensional changes in hardening and tempering

Other types, such as the M2 and M41 high-speed steels, expand about 0.2% (2 mm/m, or 0.002 in./in.) when hardened and tempered in the temperature range of 540 to 595 °C (1000 to 1100 °F) to develop full secondary hardness. Although the information in Table 2 is useful in comparing size distortion in several tool steels, the factor of shape distortion makes it impossible to use these data alone to predict dimensional changes of a particular tool made from any of these steels. Densities and thermal expansion characteristics for several classes of tool steels are presented in Table 3.

Table 3 Density and thermal expansion of selected tool steels

Shape Distortion in Tool Steels

The strength of any tool steel decreases rapidly above about 600 °C (1100 °F). At the austenitizing temperature, the yield strength is so low that plastic deformation often occurs simply from the stresses induced in the part by gravity. Therefore, long parts, large parts, and parts of complex shape must be properly supported at critical locations to prevent sagging at the hardening temperature.

Rapid heating increases shape distortion, especially in large tools and in complex tools containing both light and heavy sections. If the rate of heating is high, light sections will increase in temperature much faster than heavy sections. Likewise, the outer surfaces in heavy sections will increase in temperature much faster than the interior. Differences in thermal expansion due to the differences in temperature between light and heavy sections or between surface and interior in heavy sections will be enough to set up large stresses in the material. Under these stresses, the hotter regions will deform plastically to relieve the thermally induced stress.

Eventually, the hotter portions will reach the furnace temperature, whereas the cooler portions will continue to increase in temperature. At this point, a decrease in thermal differential begins, which will cause a partial reversal in thermal stress that produced plastic deformation when the temperature differential was high. This may cause the part to undergo further plastic deformation, but to a lesser extent than the deformation caused by the initial high-temperature differential. Such deformation will occur in a different direction.

Slow heating minimizes distortion by keeping temperature differentials low and thermal stresses within the elastic range of the material throughout the heating cycle. Ideally, all heat treatment of tool steel parts should start from a cold furnace to provide the greatest freedom from shape distortion during heating. Starting from a cold furnace is neither very practical nor energy efficient unless heat treating is being done in a vacuum furnace. When heat treating in fused salt or an atmosphere furnace, preheating the parts at one or more intermediate temperatures prior to heating them to the austenitizing temperature provides the best compromise.

During quenching, large temperature differences between surface and interior, and between light and heavy sections can cause severe shape distortion, because of thermal stress and mechanical stress produced by a martensitic transformation. This problem is most severe if the hardenability of the steel is so low that a fast cooling rate is required to obtain full hardness. In such a situation, especially when making a large or complex part, it may be best to substitute a high-hardenability, air-hardening tool steel, which requires only a slow cooling rate to fully harden. It is worth noting that water quenched steels will generally show large dimensional changes after quenching. However, because plain carbon tool steels such as W1 and W2 are shallow hardening, the amount of movement in large cross sections may be less than comparable tools made from higher-hardenability grades.

However, if lower-hardenability steels requiring liquid quenching are used, fixturing and pressure die quenching can help minimize distortion. Long symmetrical parts should be fixtured and should be quenched in the vertical position with vertical agitation of the quench mediums.

Special Techniques for Controlling Shape Distortion

Special quenching procedures such as martempering and austempering may also be useful for controlling distortion in parts that have an appropriate configuration and have been made of material of appropriate hardenability. In martempering, parts are quenched in hot molten salt fast enough to avoid transformation to high-temperature transformation products such as ferrite or pearlite. The parts are held at a bath temperature in the range from slightly above to slightly below the M_s just long enough to equalize the interior and surface temperatures. The parts are then removed from the bath and allowed to air cool to room temperature. Slow cooling through the martensitic transformation range reduces distortion as compared with rapid quenching. Martempered tools must be given the usual tempering treatment.

Austempering can be used to reduce distortion if a hardness no higher than 57 HRC is acceptable for the application. In austempering, parts are also quenched in hot molten salt but by temperature selection are forced to transform into bainite rather than martensite. Bainite forms at temperatures above those at which martensite forms. The parts must be held long enough at a temperature above M_s (usually about 230 °C, or 450 °F) to permit the austenite to transform to lower bainite. When air cooled to room temperature, austempered tools exhibit less shape distortion and generally require no subsequent tempering.

Besides being reduced through control of rates of heating and cooling, shape distortion can be reduced by employing a localized method of heating and quenching such as flame hardening, induction hardening, electron beam or laser hardening to treat only that portion of the tool that must be hardened.

Controlling out-of-roundness is important for certain precision applications, such as class C and D cutting hobs made of high-speed steels. Class C and D hobs must be held close to size limits because they are not ground to size after heat treatment, but rather are used in the unground condition.

Normal size distortion in hardening and tempering can be accommodated by making the tool slightly oversize or slightly undersize, as required, before heat treating. High-speed steel bars, however, have been observed to go out-of-round as much as 0.05 mm (0.002 in.) during heat treatment. The pattern of size distortion shown in Fig. 2(a) can occur. It appears to be related to the initial shape of the cast ingot and to the specific primary-mill processing used to reduce the ingot into bars. By changing steel-making, forgings, and rolling procedures, out-of-roundness has been reduced to the smaller differential pattern shown in Fig. 2(b), where the difference between high and low points is only 0.005 mm (0.0002 in.).

High-speed steel bars made this way are marketed by a few tool steel producers as "close tolerance hob stock." An even better method of combating out-of-roundness is to use high-speed tool steel bars made from hot isostatically pressed powders, which maintain the best possible symmetry during conventional heat treatment (see the discussion of powder metallurgy steels later in this article).

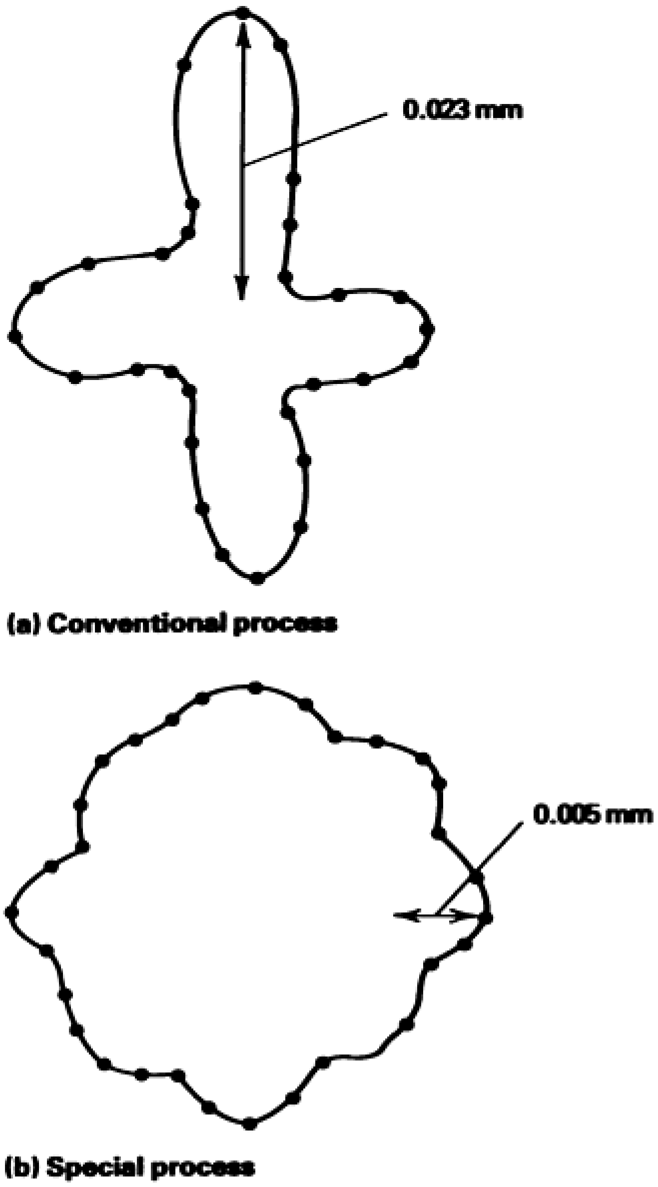

Fig. 2 Typical diameter changes during heat treatment for high-speed steel bars. Drawings produced by calculation from precision measurements of diameter. Charts are plots on polar coordinates depicting variations in diameter after heat treatment for a bar that was round within ±1.25 μm (±0.00005 in.) before heat treatment.

Stabilization involves reducing the amount of retained austenite in heat-treated material. Retained austenite can slowly transform and produce distortion if the material is later heated or subjected to stress. Stabilization also reduces internal (residual) stress, making distortion in service less likely to occur. Stabilization is most important for tools that must retain their exact size and shape over long periods (that is, gages and blocks).

If the tool steel chosen provides the required hardness after tempering at a relatively high temperature, it is possible to reduce the amount of retained austenite and the internal stress by multiple tempering. Initial tempering reduces internal stress and conditions the retained austenite so that it can transform to martensite on cooling from the tempering

temperature. A second or third retempering is usually necessary to reduce the internal stress set up by the transformation of retained austenite.

Single or repeated cold treatment to a temperature below M_f will cause most of the retained austenite to transform to martensite in plain carbon or low-alloy tool steels that must be tempered at low temperatures to achieve the hardness required. Cold treatment may be applied either before or after the first temper. If, however, the tools tend to crack because of the additional stress induced by dimensional expansion during cold treatment, it is generally prudent to apply cold treatment after first tempering of the tools. When cold treatment is applied after the first temper, the amount of retained austenite that transforms during the cold treatment may be considerably less than desired because some of the austenite may have been stabilized by tempering prior to cold treating. Cold treatment is usually done in a commercial refrigeration unit capable of attaining -70 to -95 °C (-100 to -140 °F). Tools must be retempered promptly after return to room temperature following cold treatment to reduce internal stress and to increase the toughness of the newly formed martensite.

For some tools, a small percentage of retained austenite is desirable for improving toughness and providing a favorable internal stress pattern that will help the tool to withstand service stresses. For these tools, a full stabilizing treatment may actually result in tools that are unfit to perform their required functions.

Temper Straightening of Martempered Tool Steels. Temper straightening is used for correcting distortion caused by heat treatment. The workpiece first is tempered to a hardness somewhat higher than required, and then clamped in a straightening fixture and tempered to the required hardness. The greater the hardness difference between the first and the corrective tempering operations, the more accurate the dimensions will be. Temper straightening is most successful at hardness levels of 55 HRC and lower.

Deep-hardening alloy and tool steels that are being martempered to minimize distortion should be held straight during the cooling period after austenitizing and until the completion of martempering. If straightness is not maintained throughout martempering, the workpiece will warp as martensite continues to form. Straightening should be done below 480 °C (900 °F). Cold bars or chills contacting the high side will more rapidly extract the heat from the workpiece and aid in straightening.

Other Considerations. One of the most common instances of dimensional change in steel articles is the warpage that occurs during the heating operation and that is often mistaken for a dimensional change occurring in the quench. It will be noted that on heating, a relatively large expansion takes place, and that at the transformation temperature, a slight contraction occurs. Because this contraction occurs when the steel is hot and very plastic, it is not likely to lead to cracking. However, the continuous expansion on heating will cause heavy objects or long slim objects to warp if not properly supported, if the rate of heating is too great or if nonuniform heating occurs. It is necessary to emphasize the importance of proper support for any article to be heated to a high temperature, because at this temperature the lack of strength will often allow the steel to bend under its own weight. Warpage and dimensional changes can also arise on heating from machining stresses and from unbalanced design. Slow rates of heating offer less danger of either occurring than fast rates of heating because at any one time the temperature gradients throughout the steels are less.

Excessively high austenitizing temperatures in tool steels will lead to excessive grain growth and a more stabilized austenite. This overheated condition along with the larger thermal gradients experienced during heating and quenching will result in irregular dimensional changes.

Another factor that will influence shape distortion is surface chemistry variation. For example, when lower or higher carbon concentrations exist, as in decarburization or carburization, the surface transformation temperature will be changed. The difference between the surface and the subsurface transformation will set up compressive or tensile stresses that can cause distortion and/or cracking. Elimination of surface mill decarburization or carburization by machining or grinding prior to heat treatment are recommended to eliminate such effects.

Shape change caused by mechanical thermal stresses prior to heat treatment can be addressed by stress relieving. Mechanical sources such as forming, grinding, or machining can set up nonuniform residual stresses. Brazing, welding, and torch heating can cause thermal residual stresses. These residual stresses remain in the component until thermally relieved. As the component is heated, the steel will yield plastically at the point where the hot yield strength and residual stress level coincide. The creep deformation occurs simultaneously with any stress relaxation. Localized mechanical stresses such as stamped identification marks, machining marks, sharp corners, and changes in section size will have a

significant influence on the degree and location of the shape distortion. A separate stress-relieving cycle by heating to approximately 650 °C (1200 °F) and air cooling allows the control of mechanically or thermally induced residual stress.

Upon cooling from the stress relief, the part may be distorted, but can be easily corrected in the annealed condition with an additional operation of straightening, machining, or grinding. In many situations where extensive machining is required, a good practice is to rough machine, stress relieve, and then finish machine or grind using light passes. Annealing in place of stress relieving is acceptable and preferred if considerable welding has been performed.

Preheating as the initial phase of hardening will provide a stress-relieving effect. However, distortion will manifest itself and if allowed to exist through the hardening operation, the effect of stress relieving will be lost because straightening of a hardened part is very difficult to accomplish.

Fundamentals such as the technique of placing the tools in a high heat furnace as well as racking and handling methods must be considered as potential causes of shape distortion. Uniform support of pans in a furnace is important to prevent sagging, particularly at high heat temperatures for long, slender sections. Large parts must be raised off the hearth plate to ensure satisfactory heat circulation and more even heating and cooling. Because tool steel is austenitic when it is removed from the high heat furnace, care must be exercised in transferring the load. Preferably, the parts should be placed on trays that can be grasped to remove the load. If the individual part must be handled with tongs, avoid holding it at the thinner sections, which will lose heat rapidly and might bend more easily.

Powder Metallurgy Steels

In recent years, tool steels with improved properties have been produced by the powder metallurgy (P/M) process.

The basic production routes now in commercial use for P/M tool steels are summarized in Fig. 3. All these processes use gas-or water-atomized powders and either hot isostatic pressing (HIP), mechanical compaction (extrusion, forging, and so on), or vacuum sintering for densification. The basic difference among these processes is that the use of gas atomization will yield spherical particles, while water atomization will produce angular particles of significantly higher oxygen content. The angular particles can be cold pressed to provide a compact that has sufficient mechanical strength to be handled and processed directly, while the spherical gas-atomized powder must be encapsulated prior to densification. The most widely used of the aforementioned production practices utilize gas atomization and HIP.

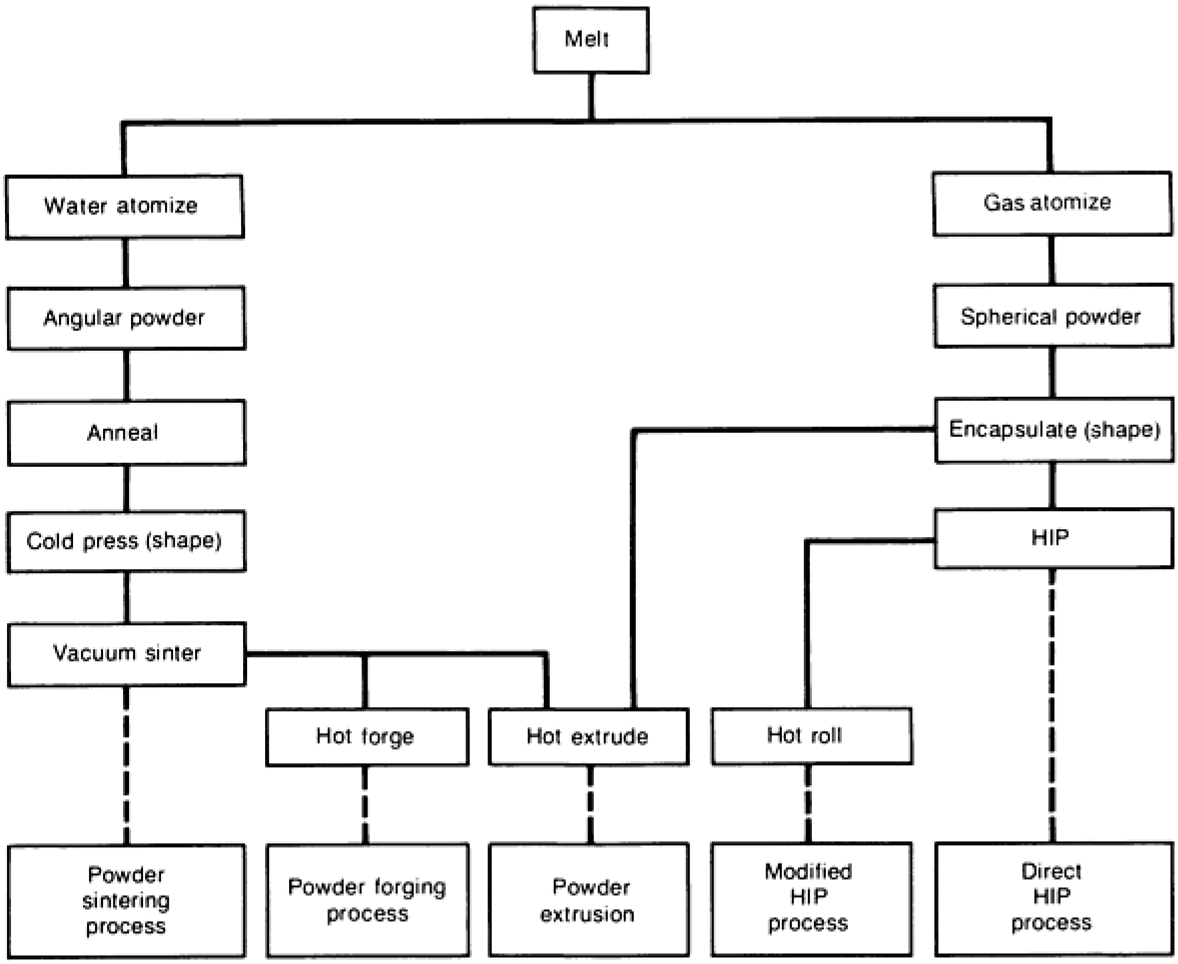

Fig. 3 Current manufacturing processes for P/M tool steels. Source: *ASM Handbook*, Volume 1, formerly 10th Edition *Metals Handbook*

P/M tool steels have two major advantages: complete freedom from macrosegregation and porosity, and uniform distribution of extremely fine carbides. These characteristics provide deeper hardening and faster response to hardening conditions (see Fig. 4). The latter is important, particularly for molybdenum high-speed steels, which tend to decarburize rapidly at austenitizing temperatures. P/M products also show less out-of-roundness distortion in large-diameter bars (see Table 4).

Table 4 Out-of-roundness distortion in large-diameter bars of M2S tool steel

Bar diameter		**Production method**	Typical out-of-roundness[(a)]	
mm	**in.**		**mm**	in.
75	3	P/M	0.008	**0.0003**
		Conventional	0.020	**0.0008**
125	5	P/M	0.013	**0.0005**

		Conventional	0.033	**0.0013**
190	7.5	P/M	0.015	**0.0006**
		Conventional	**0.051**	**0.0020**

(a) Maximum diameter minus minimum diameter after normal hardening treatment

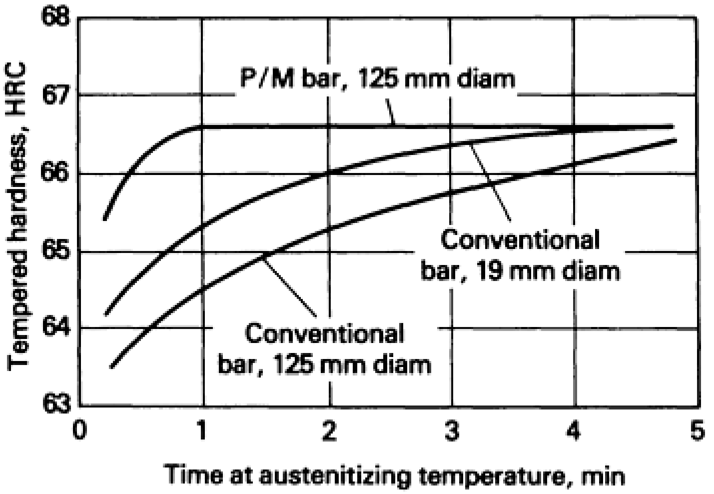

Fig. 4 Comparison of response to hardening for P/M and conventionally produced bars of M25 (HC) tool steel. Hardness at midradius was evaluated for bars oil quenched from 1200 °C (2200 °F) and tempered 2 + 2 + 2 h at 550 °C (1025 °F).

When sulfur is added to P/M tool steels, they exhibit a very fine homogeneous distribution of sulfides. This uniform sulfide distribution promotes better machinability. After heat treating, the refined, hardened, and tempered P/M tool steels exhibit better grindability and greater toughness than conventionally processed (cast and wrought) tool steels. As of 1990, more than 30 different P/M tool steel compositions were commercially available. Many of these correspond directly to AISI wrought counterparts. More detailed information on processing and properties of P/M tool steels can be found in the article "P/M Tool Steels" in Volume 1 of *ASM Handbook*, formerly 10th Edition *Metals Handbook.*

Maraging Steels

A group of alloys known as 18% Ni maraging steels are commonly used for tooling. These maraging steels are chosen for a variety of reasons, not the least of which is their freedom from distortion associated with the austenite to martensite transformation. Maraging steels are supplied by producers in a soft martensitic condition, approximately 28 to 35 HRC, referred to as the solution treated or solution annealed condition. In this solution treated condition, the alloy can be formed, machined, and conventionally fabricated. The full hardness of the alloy is achieved by a simple aging treatment, usually 3 to 6 h at approximately 480 °C (900 °F) followed by air cooling. This aging or precipitation hardening treatment is not accompanied by an austenite/martensite phase change and therefore is not prone to the distortion prominent with other tool steels. A uniform predictable shrinkage does occur in the amount of approximately 0.025 mm/25 mm (0.001 in./in.). Because the development of hardness is essentially independent of the cooling rate from the aging temperature, full through hardness can be achieved even in massive sections with only minimal shrinkage and essentially no distortion.

Decarburization, another cause of stress and distortion in conventional tool steels, is not a factor with 18Ni maraging steels because they contain only low residual carbon levels (less than 0.025%).

Several maraging steels are available and provide a wide variety of hardness or strength levels (Table 5). The 18Ni maraging steels are alloyed to obtain a specific hardness level and are given a standard aging treatment. Choice of a specific grade will dictate that hardness. It is typically not recommended to under- or overage the alloy because some degradation of properties can occur. The system for identification of the various maraging grades incorporates a three digit number and a letter (C or T) designating the approximate tensile strength (in ksi) and the principal alloy strengthener (cobalt or titanium), respectively. For example, 18Ni C (250) is an 18% Ni maraging steel alloyed with cobalt that has a tensile strength of ~250 ksi (~1720 MPa). More detailed information on these alloys can be found in the article "Heat Treating of Maraging Steels" in this Volume.

Table 5 Typical hardening (aging) treatments and resultant hardnesses for maraging steels

Grade	**Aging treatment**[(a)]		Nominal hardness, HRC
	°C	**°F**

18Ni T (300)	480	(900)[(b)]	**53**

(a) 3 to 6 h + 1 h per additional in. (25 mm) of cross section.

(b) Aging treatment of 530 °C (990 °F) is recommended for aluminum die casting dies which result in hardness values slightly lower (~2 HRC) than indicated.

Heat Treating of Stainless Steels

Revised by Joseph Douthett, Armco Research and Technology

Introduction

HEAT TREATING of stainless steel serves to produce changes in physical condition, mechanical properties, and residual stress level, and to restore maximum corrosion resistance when that property has been adversely affected by previous fabrication or heating. Frequently, a combination of satisfactory corrosion resistance and optimum mechanical properties is obtained in the same heat treatment.

Heat Treating of Stainless Steels

Revised by Joseph Douthett, Armco Research and Technology

Austenitic Stainless Steels

In furnace loading, the high thermal expansion of austenitic stainless steels (about 50% higher than that of a mild carbon steel) should be considered. The spacing between parts should be adequate to accommodate this expansion. Stacking, when necessary, should be employed judiciously to avoid deformation of parts at elevated temperatures.

Susceptibility to Intergranular Attack

The austenitic stainless steels may be divided into five groups:

- Conventional austenitics, such as types 301, 302, 303, 304, 305, 308, 309, 310, 316, and 317
- Stabilized compositions, primarily types 321, 347, and 348
- Low-carbon grades, such as types 304L, 316L, and 317L
- High-nitrogen grades, such as AISI types 201, 202, 304N, 316N, and the Nitronic series of alloys
- Highly alloyed austenitics, such as 317LM, 317LX, JS700, JS777, 904L, AL-4X, 2RK65, Carpenter 20Cb-3, Sanicro 28, AL-6X, AL-6XN, and 254 SMO

The compositions of standard and nonstandard austenitic stainless steels are listed in Tables 1 and 2.

(a) XM designations in this column are ASTM designations for the listed alloy.

(b) Single values are maximum values unless otherwise indicated.

(c) Nominal compositions.

(d) Ref 1

Conventional austenitics cannot be hardened by heat treatment but will harden as a result of cold working. These steels are usually purchased in an annealed or cold-worked state. Following welding or thermal processing, a subsequent reanneal may be required for optimum corrosion resistance, softness, and ductility. During annealing, chromium carbides, which markedly decrease resistance to intergranular corrosion, are dissolved. Annealing temperatures, which vary somewhat with the composition of the steel, are given in Table 3 for wrought alloys and in Table 4 for the corresponding cast alloys. Table 5 includes compositions and typical microstructures for selected austenitic corrosion-resistant cast steels listed in Table 4.

Table 3 Recommended annealing temperatures for austenitic stainless steels

(a) Temperatures given are for annealing a composite structure. Time at temperature and method of cooling depend on thickness. Light sections may be held at temperature for 3 to 5 min per 2.5 mm (0.10 in.) of thickness, followed by rapid air cooling. Thicker sections are water quenched. For many of these grades, a postweld heat treatment is not necessary. For proprietary alloys, alloy producers may be consulted for details. Although cooling from the annealing temperature must be rapid, it must also be consistent with limitations of distortion.

(a) Type numbers of wrought alloys are listed only for nominal identification of corresponding wrought and cast grades. Composition ranges of cast alloys are not the same as for corresponding wrought alloys; cast alloy designations should be used for castings only.

(b) Maximum unless a range is given. The balance of all compositions is iron.

(c) Sulfur content is 0.04% in all grades except: CG-6MMN, 0.030% S (max); CF-10SMnN, 0.03% S (max); CT-15C, 0.03% S (max); CK-3MCuN, 0.010% S (max); CN-3M, 0.030% S (max); CA-6N, 0.020% S (max); CA-28MWV, 0.030% S (max); CA-40F, 0.20-0.40% S; CB-7Cu-1 and -2, 0.03% S (max). Phosphorus content is 0.04% (max) in all grades except: CF-16F, 0.17% P (max); CF-10SMnN, 0.060% P (max); CT-15C, 0.030% P (max); CK-3MCuN, 0.045% P (max); CN-3M, 0.030% P (max); CA-6N, 0.020% P (max); CA-28MWV, 0.030% P (max); CB-7Cu-1 and -2, 0.035% P (max).

(d) Molybdenum not intentionally added.

(e) CF-3A, CF-3MA, and CF-8A have the same composition ranges as CF-3, CF-3M, and CF-8, respectively, but have balanced compositions so that ferrite contents are at levels that permit higher mechanical property specifications than those for related grades. They are covered by ASTM A 351.

(f) Nb, 8 × %C min (1.0% max); or Nb + Ta × %C (1.1% max).

(g) For CN-7MS, silicon ranges from 2.50 to 3.50%.

Because carbide precipitation can occur at temperatures between 425 and 900 °C (800 and 1650 °F), it obviously is desirable that the annealing temperature should be safely above this limit. Moreover, because all carbides should be in solution before cooling begins, and because the chromium carbide dissolves slowly, the highest practical temperature consistent with limited grain growth is selected. This temperature is in the vicinity of 1095 °C (2000 °F).

Cooling from the annealing temperature must be rapid, but it must also be consistent with limitations of distortion. Whenever considerations of distortion permit, water quenching is used, thus ensuring that dissolved carbides remain in solution. Because it precipitates carbides more rapidly, type 310 invariably requires water quenching. Where practical considerations of distortion rule out such a fast cooling rate, cooling in an air blast is used. With some thin-section parts, even this intermediate rate of cooling produces excessive distortion, and parts must be cooled in still air. If cooling in still air does not provide a rate sufficient to prevent carbide precipitation, maximum corrosion resistance will not be obtained. A solution to this dilemma is the use of a stabilized grade or the low-carbon alloys.

Stabilized austenitic alloys, namely types 321, 347, 348, and Carpenter 20Cb-3, contain controlled amounts of titanium or of niobium, which render the steel nearly immune to intergranular precipitation of chromium carbide and its adverse effects on corrosion resistance. Nevertheless, these alloys may require annealing to relieve stresses, to increase softness and ductility, or to provide additional stabilization.

To obtain maximum softness and ductility, the stabilized grades are annealed at the temperatures shown in Table 3. Unlike the unstabilized grades, these steels do not require water quenching or other acceleration of cooling from the annealing temperature to prevent subsequent intergranular corrosion; air cooling is generally adequate.

When maximum corrosion resistance of the stabilized austenitic grades is required, it may be necessary to employ a heat treatment known as a stabilizing anneal. The treatment consists of holding at 845 to 900 °C (1550 to 1650 °F) for up to 5 h, depending on section thickness. It may be applied either prior to, or in the course of, fabrication, and it may be followed by short-time stress relieving at 705 °C (1300 °F) without danger of harmful carbide precipitation (see the section "Stress Relieving of Austenitic Stainless Steels" in this article).

Carpenter 20Cb-3 stainless steel is unlike the conventional stabilized austenitics (types 321, 347, and 348) because of its higher alloy content and improved corrosion resistance. This alloy normally is stabilized and annealed at 925 to 955 °C (1700 to 1750 °F). For special applications, the alloy can be annealed at higher temperatures (up to 1150 °C, or 2100 °F), but this is permissible only if the alloy will not be subject to welding or heating temperatures over 540 °C (1000 °F).

Certain restrictions on furnace atmosphere are mandatory. Furnace combustion must be carefully controlled to eliminate carburizing or excessively oxidizing conditions. Because the properties of the stabilized steels are based on their original carbon content, carbon absorption cannot be tolerated. Excessively oxidizing conditions cause the formation of a scale that is difficult to remove in subsequent descaling operations. Direct impingement of flame on the work must be prevented. The sulfur content of the furnace atmosphere, particularly in oil-fired furnaces, must be kept low; natural gas, not producer gas, should be used.

Low-carbon austenitics are intermediate in tendency to precipitate chromium carbides to the stabilized and unstabilized grades. Carbon content (0.03% max) is low enough to reduce precipitation of intergranular carbides. This characteristic of limited sensitization is of particular value in welding, flame cutting, and other hot-working operations. They do not require the quenching treatment that unstabilized grades require to retain carbon in solid solution. Nevertheless, the low-carbon alloys are not satisfactory for long-time service in the sensitizing temperature range of 540 to 760 °C (1000 to 1400 °F) because they are not completely immune to the formation of carbides deleterious to corrosion resistance. Recommended annealing temperatures for the low-carbon alloys are given in Table 3.

The effects of sensitization and susceptibility to general corrosion vary among the low-carbon alloys, depending on their chemical composition. Because they contain molybdenum, types 316L and 317L are susceptible to σ-phase formation as a result of long-time exposure at 650 to 870 °C (1200 to 1600 °F). However, the corrosion resistance of these grades can be

improved by employing a stabilizing treatment (ASTM A 262C), consisting of holding at 885 °C (1625 °F) for 2 h, prior to stress relieving at 675 °C (1250 °F). After receiving the stabilizing heat treatment, these alloys pass the copper-copper sulfate 16% sulfuric acid test (ASTM A 262, Practice E) for freedom from intergranular carbide precipitation.

Magnetic Permeability. The low-carbon alloys are frequently used in the production of articles requiring low magnetic permeability. These materials are nonmagnetic in the fully annealed condition, with permeabilities below 1.02 max at 0.02 T (200 G) but may develop ferromagnetic qualities as a result of cold working during fabrication. Cold working may generate some low-carbon martensite, which is strongly magnetic. Fusion welding with a low-nickel filler rod is another possible cause of magnetism. Magnetism due to any of these causes can be eliminated by a full anneal to restore the alloy to its fully austenitic condition.

High-nitrogen austenitic stainless steels are heat treated in the same manner and are subject to the same problems (carbide precipitation and distortion) as conventional austenitics. They cannot be hardened by heat treatment but will harden by cold working. High-nitrogen austenitics are annealed to ensure maximum corrosion resistance, softness, and ductility. Rapid cooling is preferred. Annealing temperature ranges are listed in Table 3.

Highly alloyed austenitic stainless steels contain large amounts of molybdenum to provide very good resistance to chloride corrosion. They usually are produced with low carbon to avoid sensitization and may contain copper for increased acid resistance. These alloys are austenitic in the mill-annealed condition but may form σor δ ferrite phases under certain conditions of heat treatment or service. Those phases may be detrimental to corrosion resistance and mechanical properties. Annealing temperatures are confined to a narrow range to avoid σ-phase formation at lower temperature, or δ ferrite at higher temperature. Recommended annealing temperatures are given in Table 1. Rapid cooling following annealing is usually advisable, especially in heavy sections. Stress-relief treatments may be used below the annealing temperature range, but holding times should be held to a minimum to avoid ω phase and sensitization problems.

Magnetic Permeability. The more highly alloyed austenitic grades, along with the high-nitrogen grades such as 316N, the Nitronic family, and Carpenter 18-18 Plus, will not develop low-carbon martensite with cold work and thereby do not require a full anneal to reduce magnetic permeability. The permeability of these alloys will remain below 1.02 even with significant amounts of cold work.

Bright Annealing of Austenitic Stainless Steels

All grades of austenitic stainless steel can be bright annealed in either pure hydrogen or dissociated ammonia, provided the dew point of the atmosphere is less than -50 °C (-60 °F) and the workpieces, upon entering the furnace, are dry and scrupulously clean. The furnaces used in bright annealing must be clean, moisture-free, and tight if low dew points are to be maintained. If a low dew point is not maintained, a thin greenish oxide will form on the work. This oxide is very difficult to remove in subsequent descaling operations.

To maintain close control of dew point, atmosphere samples should be withdrawn from the furnace at frequent intervals and tested or continuously monitored, as in most commercial operations. Traces of oxygen in hydrogen gas can be removed before the gas enters the furnace by passing the gas through a catalytic tower that causes excess oxygen to combine with the hydrogen to form water vapor. The gas is then passed through activated alumina to remove moisture.

In using dissociated ammonia, it is important that maximum dissociation be obtained before the gas enters the furnace. The presence of any undissociated ammonia will result in objectionable nitriding action. Because the undissociated gas is entirely soluble in water, its removal can be easily accomplished. However, the remaining fully dissociated product must be processed through drying towers to restore the required low dew point.

Stress Relieving of Austenitic Stainless Steels

Austenitic stainless steels have good creep resistance; consequently, these steels must be heated to about 900 °C (1650 °F) to attain adequate stress relief. In some instances, heating to the annealing temperature may be desirable. Holding at a temperature lower than about 870 °C (1600 °F) results in only partial stress relief. The most effective stress-relieving results are achieved by slow cooling. Quenching or other rapid cooling, as is normal in the annealing of austenitic stainless steel, will usually reintroduce residual stresses. Stress relieving is only necessary when austenitic stainless parts are subjected to corrosive conditions conducive to stress corrosion or intergranular corrosion failures.

Selection of Treatment. Selection of an optimum stress-relieving treatment is difficult because heat treatments that provide adequate stress relief can impair the corrosion resistance of stainless steel, and heat treatments that are not harmful to corrosion resistance may not provide adequate stress relief. To avoid specifying a heat treatment that might prove harmful, ASME Code neither requires nor prohibits stress relief of austenitic stainless steel.

Metallurgical characteristics of austenitic stainless steels that may affect the selection of a stress-relieving treatment are discussed below:

- *Heating in the range from 480 to 815 °C (900 to 1500 °F):* Chromium carbides will precipitate in the grain boundaries of wholly austenitic unstabilized grades. In partially ferritic cast grades, the carbides will precipitate initially in the discontinuous ferrite pools rather than in a continuous grain-boundary network. After prolonged heating such as is necessary for heavy sections, however, grain-boundary carbide precipitation will occur. For cold-worked stainless, carbide precipitation may occur as low as 425 °C (800 °F); for types 309 and 310, the upper limit for carbide precipitation may be as high as 900 °C (1650 °F). In this condition, the steel is susceptible to intergranular corrosion. By using stabilized or extra-low-carbon grades, these intergranular precipitates of chromium carbide can be avoided
- *Heating in the range from 540 to 925 °C (1000 to 1700 °F):* The formation of hard, brittle σ phase may result, which can decrease both corrosion resistance and ductility. During the times necessary for stress relief, σ will not form in fully austenitic wrought, cast, or welded stainless. However, if the stainless is partly ferritic, the ferrite may transform to σ during stress relief. This is generally not a problem in wrought stainless steels because they are fully austenitic; however, some wrought grades--particularly types 309, 309Cb, 312, and 329--may contain some ferrite. Furthermore, the composition of most austenitic stainless welds and castings is intentionally adjusted so that ferrite is present as a deterrent to cracking. The niobium- (columbium)-containing cast grade CF-8C normally contains 5 to 20% ferrite, which is more likely to transform to σ than the niobium-free ferrite in the unstabilized CF-8 grade
- *Slow cooling an unstabilized grade (other than an extra-low-carbon grade):* Through either of the above temperature ranges, slow cooling may allow sufficient time for these detrimental effects to take place
- *Heating at 815 to 925 °C (1500 to 1700 °F):* The coalescence of chromium carbide precipitates or σ phase will occur, resulting in a form less harmful to corrosion resistance or mechanical properties
- *Heating at 955 to 1120 °C (1750 to 2050 °F):* This annealing treatment causes all grain-boundary chromium carbide precipitates to redissolve and transforms σ back to ferrite, as well as fully softening the steel. Long heating times (>1 h) may even dissolve some of the ferrite present and further reduce the probability of σ reforming upon slow cooling
- *Stress relieving to improve the notch toughness:* Unlike carbon and alloy steels, austenitic steels are not notch sensitive. Consequently, stress relieving to improve notch toughness would be of no benefit. Notch-impact strength may actually be decreased if the steel is stress relieved at a temperature at which chromium carbide is precipitated or σ phase forms

Although stabilized alloys do not require high-temperature annealing to avoid intergranular corrosion, the stress-relieving temperature exerts an influence on the general corrosion resistance of these alloys. Figure 1 shows the effect of stress relieving for 2 h at various temperatures on the corrosion rate of type 347 stainless steel in boiling 65% nitric acid. The corrosion resistance of type 347 in boiling nitric acid is better when the material is treated at 815 to 870 °C (1500 to 1600 °F) than when treated at 650 to 705 °C (1200 to 1300 °F). The 650 to 705 °C (1200 to 1300 °F) stress relief may be promoting the formation of a small quantity of chromium carbides as a result of free carbon not previously tied up as niobium carbides.

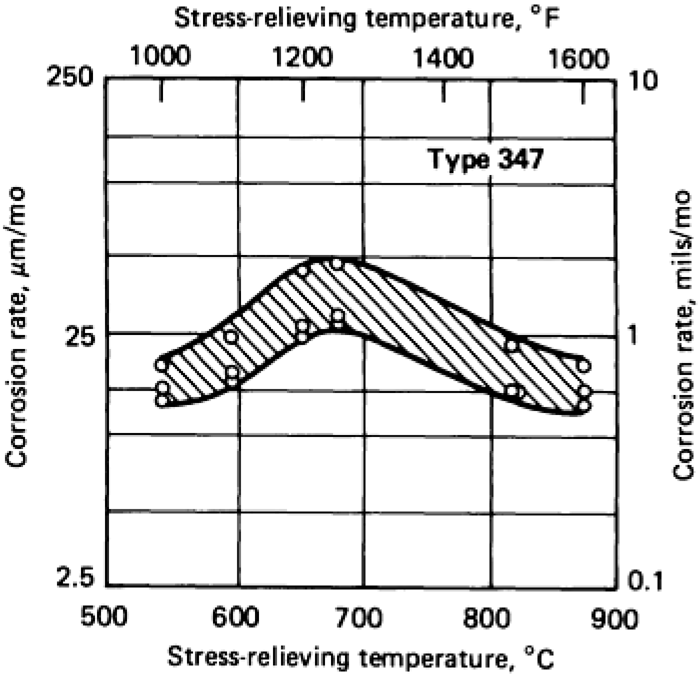

Fig. 1 Effect of stress relieving on corrosion rate of type 347 stainless steel in boiling 65% HNO_3. All stress-relief treatments lasted 2 h.

Figure 2 shows how the percentage of stress relief increases with an increase in stress-relieving temperature for type 347 stainless steel. These data also demonstrate the relative unimportance of holding time.

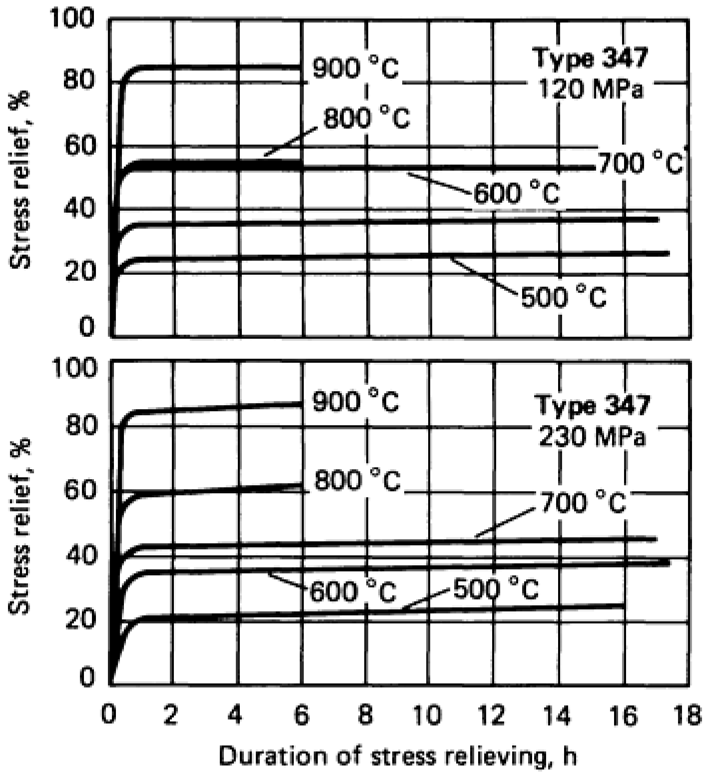

Fig. 2 Stress relief obtained in type 347 stainless steel, as a function of temperature, initial stress, and time at

temperature

General Recommendations. In the selection of the proper stress-relieving treatment, consideration must be given also to the specific material used, fabrication procedures involved, and to the design and operating conditions of the equipment. Stress relieving generally is not advisable unless the service environment is known or suspected to cause stress corrosion. If stress relieving seems warranted, due regard should be given the metallurgical factors and their effect on the steel in the intended service. The use of stabilized or extra-low-carbon grades is an advantage in view of the greater latitude allowed in stress relieving.

Table 6 gives suggested stress-relieving treatments for service applications and environments. Because of the varying degrees of stress relief that may be required, number of different grades of stainless in use, many fabricating procedures that may be employed, and the multitude of service requirements, many alternative treatments are indicated in Table 6 to allow selection of the stress-relieving treatment best suited to particular circumstances.

Table 6 Stress-relieving treatments for austenitic stainless steels

Application or desired characteristics	**Extra-low-carbon grades, such as 304L and 316L**	Suggested thermal treatment[a]	
		Stabilized grades, such as 318, 321, and 347	Unstabilized grades, such as 304 and 316
Severe stress corrosion	A, B	B, A	[b]

No stress corrosion	None required	None required	**None required**
Intergranular corrosion	A, C[c]	A, C, B[c]	**C**
Stress relief after severe forming	A, C	A, C	**C**
Relief between forming operations	A, B, C	B, A, C	**C**[d]
Structural soundness[e]	A, C, B	A, C, B	**C**

(a) Thermal treatments are listed in order of decreasing preference. A: Anneal at 1065 to 1120 °C (1950 to 2050 °F) and then slow cool. B: Stress relieve at 900 °C (1650 °F) and then slow cool. C: Anneal at 1065 to 1120 °C (1950 to 2050 °F) and then quench or cool rapidly. D: Stress relieve at 900 °C (1650 °F) and then quench or cool rapidly. E: Stress relieve at 480 to 650 °C (900 to 1200 °F) and then slow cool. F: Stress relieve at below 480 °C (900 °F) and then slow cool. G: Stress relieve at 205 to 480 °C (400 to 900 °F) and then slow cool (usual time, 4 h per inch of section).

(b) To allow the optimum stress-relieving treatment, the use of stabilized or extra-low-carbon grades is recommended.

(c) In most instances, no heat treatment is required, but where fabrication procedures may have sensitized the stainless steel the heat treatments noted may be employed.

(d) Treatment A B, or D also may be used, if followed by treatment C when forming is completed.

(e) Where severe fabricating stresses coupled with high service loading may cause cracking. Also, after welding heavy sections

Results Obtained by Various Treatments. Austenitic stainless steels have in many instances been stress relieved at temperatures normally used for carbon steels (540 to 650 °C, or 1000 to 1200 °F). Although at these temperatures virtually all residual stress is relieved in carbon steel, only 30 to 40% of the residual stress is relieved in austenitic stainless (Fig. 2). Because the treatment does not provide adequate stress relief, stainless stress relieved in this temperature range is often susceptible to stress corrosion. Table 7 shows the residual stresses remaining in solid austenitic stainless steels after being stress relieved for various times at temperatures ranging from 595 to 1010 °C (1100 to 1850 °F).

Table 7 Residual stresses in welded austenitic stainless steel before and after various treatments

Treatment			Residual stress	
Temperature		**Time, h**		
°C	**°F**		**MPa**	ksi
After welding 235 mm (9.25 in.) OD, 165 mm (6.5 in.) ID pipe

Annealing and Water Quenching. Numerous instances have been reported in which satisfactory service was obtained for vessels and parts that were stress relieved by being annealed (at 1065 to 1120 °C, or 1950 to 2050 °F) and water quenched. However, it is unlikely that these products were subjected to service environments conducive to severe stress corrosion (the presence of chlorides is one such hostile environment) because a water quench will almost always reintroduce high residual stresses.

Intergranular Corrosion. In a number of instances, partially stress-relieved stainless steel parts have failed through intergranular corrosion.

For example, partially stress relieved (at 620 to 650 °C, or 1150 to 1200 °F) type 316 stainless steel hardware used in coastal steam stations failed due to intergranular attack in seawater over a span of less than 6 mo.

Another typical case of intergranular corrosion involved a type 304 stainless steel heat exchanger (partially stress relieved at 650 °C, or 1200 °F) for 2 h and furnace cooled) that failed within 7 days.

Prevention of Stress Corrosion by Stress Relieving. A number of instances have been recorded in which beneficial effects were derived from an adequate stress-relief treatment.

Heaters made of type 316L failed after a few weeks of service while in contact with acid organic chloride and ammonium chloride, but those that were stress relieved at 955 °C (1750 °F) were completely free of stress-corrosion cracking (SCC) after 4 years of service under the same conditions.

Typically, when two type 316L stainless steel vessels are used in 85% phosphoric acid service, the vessel not stress relieved underwent extensive stress corrosion, whereas the stress-relieved (540 °C, or 1000 °F) vessel was completely free of any stress corrosion. This illustrates that even though a stainless steel component may not be completely stress relieved, reducing the stress level may totally prevent stress corrosion.

Stress relief of unstabilized grades of stainless at 900 °C (1650 °F) will result in some intergranular carbide precipitation, and in some instances a small amount of intergranular attack is preferable to failure within a few weeks by stress-corrosion cracking. Moreover, the intergranular attack probably could be avoided by using an extra-low-carbon or stabilized grade of austenitic stainless steel.

Ferritic Stainless Steels

The ferritic stainless steels may be divided into two groups:

- Conventional ferritics such as types 405, 409, 430, 434, 439, and 446
- Low-interstitial ferritics such as types 444, E-Brite, Sea-Cure, AL 29-4C, and AL 29-4-2

The ferritic stainless steels are not normally hardened by quenching but rather develop minimum hardness and maximum ductility, toughness, and corrosion resistance in the annealed and quenched condition. Therefore, the only heat treatment applied to the ferritics is annealing. This treatment relieves stresses developed during welding or cold working and provides a more homogeneous structure by dissolving transformation products formed during welding. Postweld heat treatment of the low-interstitial ferritic stainless steels is generally unnecessary and is frequently undesirable. Table 8 summarizes current annealing practices for the ferritic grades.

(a) Postweld heat treating of the low-interstitial ferritic stainless steels is generally unnecessary and frequently undesirable. Any annealing of these grades should be followed by water quenching or very rapid cooling.

Austenite-Martensite Embrittlement. When grades such as 430 and 434 are cooled rapidly from above 925 °C (1700 °F), they may become brittle from austenite transforming to as much as 30% martensite. This may be corrected by a tempering treatment such as 650 to 790 °C (1200 to 1450 °F), which softens the alloy.

After such a treatment, some carbide formation can occur. After severe cold working, an anneal under 925 °C (1700 °F) is recommended to avoid further sensitization. Stabilized ferritics such as 439 or 444 avoid the austenite-martensite embrittlement concern by removing the strong austenite-forming elements (carbon plus nitrogen) from solution.

475 °C (885 °F) Embrittlement. A potentially harmful form of embrittlement common to the ferritic grades can develop from prolonged exposure to, or slow cooling within, the temperature range from about 370 to 540 °C (700 to 1000 °F), with the maximum rate of embrittlement occurring at about 475 °C (885 °F). The embrittlement is caused by precipitation of the α' phase, and the effects of embrittlement increase rapidly with chromium content. Lower-chromium alloys such as type 409 show little tendency to embrittle with 475 °C (885 °F) exposure. Certain heat treatments must be controlled to avoid embrittlement. The brittle condition can be eliminated by the treatments listed in Table 8, using temperatures clearly above the upper boundary of embrittlement, followed by rapid cooling to prevent a recurrence.

Intermetallic Phase Embrittlement. Intermetallic phases, such as σ, χ, and Laves, may form at elevated temperatures in ferritic stainless steels containing more than about 14% Cr and/or the addition of elements such as niobium or molybdenum. These intermetallic phases increase hardness (sometimes usefully) and decrease ductility, notch toughness, and corrosion resistance. The temperature range over which these phases form is approximately 595 to 1000 °C (1100 to 1830 °F). Generally, such phases are of most concern when affected parts are cooled to room temperature. At elevated temperatures, the phases do not appear to be a major problem from a ductility or toughness standpoint. In the case of Laves nphase, such intermetallics can even improve high-temperature creep strength. Figure 3 compares stress-rupture properties of selected ferritic and austenitic stainless steels.

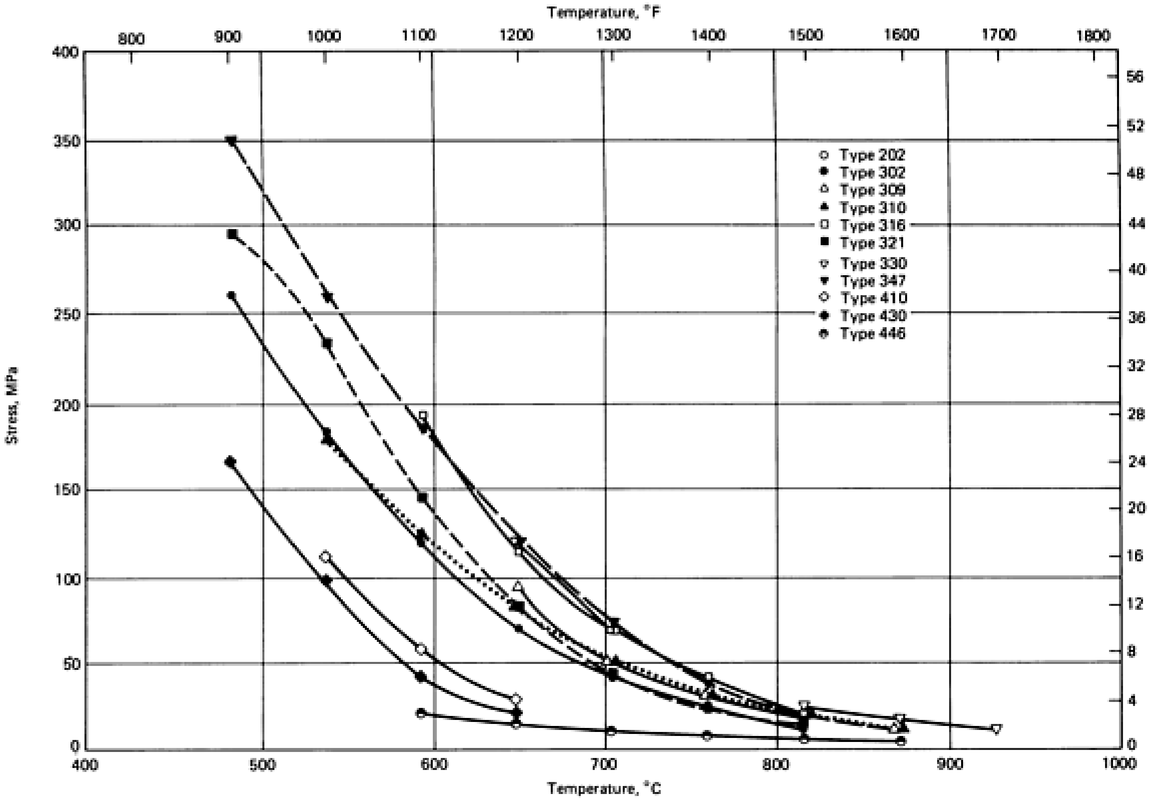

Fig. 3 10 000-h stress-rupture strength of wrought stainless steels. All samples were annealed with the

exception of type 410 (heat treated at 980 °C, or 1800 °F, for $\frac{1}{2}$ h, oil quenched, tempered at 650 °C, or 1200 °F, for 2 h and then air cooled). Extrapolated data were used for all curves.

Intermetallic phase embrittlement is primarily a service problem involving long exposures at elevated temperatures. These phases can be dissolved by heating to above 1000 °C (1830 °F).

Duplex Stainless Steels

Duplex stainless steels consist of a mixed microstructure of austenite and ferrite. Some duplex stainless steels are rich in ferrite, others in austenite, and others are equally balanced. Compared with type 316, the annealed duplex alloys provide improved resistance to chloride stress-corrosion cracking. Although the duplex grades are generally not as resistant to SCC as the low-interstitial ferritics, they are normally available in heavier section thicknesses. Another useful characteristic of the duplex grades is that they typically have yield strengths more than twice that of the conventional austenitic stainless steels. In thicker sections, the duplex alloys are more impact resistant than ferritic alloys.

Duplex stainless steels, such as SAF 2205, AF 22, DP 3, and Ferralium alloy 255, are alloyed with 0.15 to 0.20% N. This minimizes alloy element segregation between the ferrite and austenite, thereby improving the as-welded corrosion resistance compared with the type 329 alloy. The nitrogen addition also increases the precipitation of austenite during casting and welding and prevents high-ferrite content in rapidly cooled welds. Recommended annealing temperatures for duplex stainless steels are listed in Table 9.

Table 9 Recommended annealing temperatures for selected duplex stainless steels

(a) Cooling from the annealing temperature must be rapid, but it also must be consistent with

limitations of distortion.

Martensitic Stainless Steels

The heat treating of martensitic stainless steel is essentially the same as for plain-carbon or low-alloy steels, in that maximum strength and hardness depend chiefly on carbon content. The principal metallurgical difference is that the high alloy content of the stainless grades causes the transformation to be so sluggish, and the hardenability to be so high, that maximum hardness is produced by air cooling in the center of sections up to approximately 305 mm (12 in.) thick.

Surface hardness ranges for the various heat-treated conditions from fully annealed to fully hardened are given in Fig. 4.

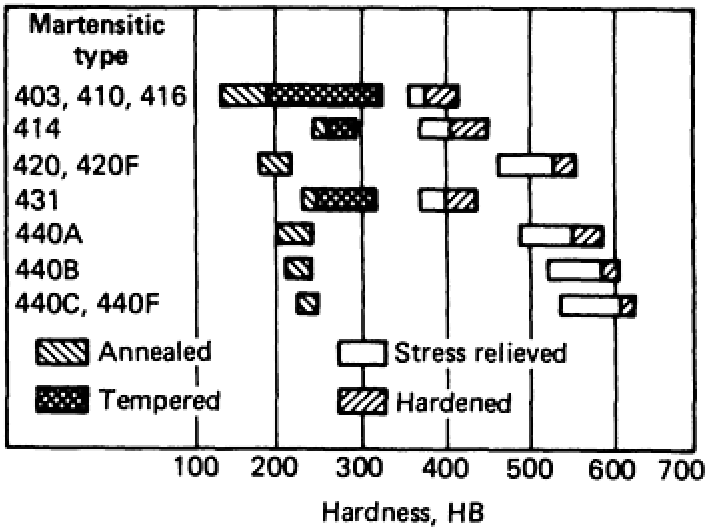

Fig. 4 Effect of heat treatments on the hardness of wrought martensitic stainless steels

The martensitic stainless steels are more sensitive to heat-treating variables than are carbon and low-alloy steels; rejection rates due to faults in heat treating are correspondingly high.

Prior Cleaning. To avoid contamination, all parts and heat-treating fixtures must be cleaned thoroughly before they are placed in the furnace. Proper cleaning is particularly important when the heat treatment is to be performed in a protective atmosphere. Grease, oil, and even location lines made by an ordinary lead pencil can cause carburization. Perspiration stains from fingerprints are a source of chloride contamination and may cause severe scaling in oxidizing atmospheres. Furthermore, a protective atmosphere cannot be effective unless it is permitted to make unobstructed contact with metal surfaces.

Preheating. Martensitic stainless steels normally are hardened by being heated to the austenitizing range of 925 to 1065 °C (1700 to 1950 °F) and then cooled in air or oil.

The thermal conductivity of stainless steels is characteristically lower than that of carbon and alloy steels. Accordingly, high thermal gradients and high stresses during rapid heating may cause warpage and cracking in some parts. To avoid these problems, preheating is usually recommended in the treatment of martensitic stainless steels. In annealing or hardening, the following parts should be preheated:

- Heavy section parts
- Parts with both thin and thick sections
- Parts with sharp corners and reentrant angles
- Heavily ground parts
- Parts machined with heavy deep cuts

- Parts that have been cold formed or straightened
- Previously hardened parts that are being reheat treated

Preheating is normally accomplished at 760 to 790 °C (1400 to 1450 °F), and heating need be continued only long enough to ensure that all portions of each part have reached the preheating temperature. Large heavy parts are sometimes preheated at approximately 540 °C (1000 °F) prior to the 790 °C (1450 °F) preheat. Types 403, 410, and 416 require less preheating than the higher-carbon types 431, 420, and 440 grades.

Austenitizing temperatures, soaking times, and quenching media are summarized in Table 10. When maximum corrosion resistance and strength are desired, the steel should be austenitized at the high end of the temperature range. For alloys that are to be tempered above 565 °C (1050 °F), the low side of the austenitizing range is recommended because it enhances ductility and impact properties.

Table 10 Procedures for hardening and tempering wrought martensitic stainless steels to specific strength and hardness levels

440B	1010-1065	1850-1950	Air or oil[(e)]	150	370	300	700	. . .	. . .	53-59

440C, 440F	1010-1065	1850-1950	Air or oil[(c)]	. . .	160	. . .	325	. . .	. . .	60 min
				. . .	190	. . .	375	. . .	. . .	58 min
				. . .	230	. . .	450	. . .	. . .	57 min
				. . .	355	. . .	675	. . .	. . .	52-56

(a) Preheating to a temperature within the process annealing range (see Table 12) is recommended for thin-gage parts, heavy sections, previously hardened parts, parts with extreme variations in section or with sharp reentrant angles, and parts that have been straightened or heavily ground or machined, to avoid cracking and minimize distortion, particularly for types 420, 431, and 440A, B, C, and F.

(b) Usual time at temperature ranges from 30 to 90 min. The low side of the austenitizing range is recommended for all types subsequently tempered to 25 to 31 HRC; generally, however, corrosion resistance is enhanced by quenching from the upper limit of the austenitizing range.

(c) Where air or oil is indicated, oil quenching should be used for parts more than 6.4 mm ($\frac{1}{4}$ in.) thick; martempering baths at 150 to 400 °C (300 to 750 °F) may be substituted for an oil quench.

(d) Generally, the low end of the tempering range of 150 to 370 °C (300 to 700 °F) is recommended for maximum hardness, the middle for maximum toughness, and the high end for maximum yield strength. Tempering in the range of 370 to 565 °C (700 to 1050 °F) is not recommended because it results in low and erratic impact properties and poor resistance to corrosion and stress corrosion.

(e) For minimum retained austenite and maximum dimensional stability, a subzero treatment -75 ± 10 °C (-100 ± 20 °F) is recommended; this should incorporate continuous cooling from the austenitizing temperature to the cold transformation temperature.

The effect of austenitizing temperature on the as-quenched hardness of three martensitic grades is shown in Fig. 5. The hardness increases with increasing austenitizing temperature to about 980 °C (1800 °F), then decreases because of austenite retention and (occasionally) the formation of δ ferrite.

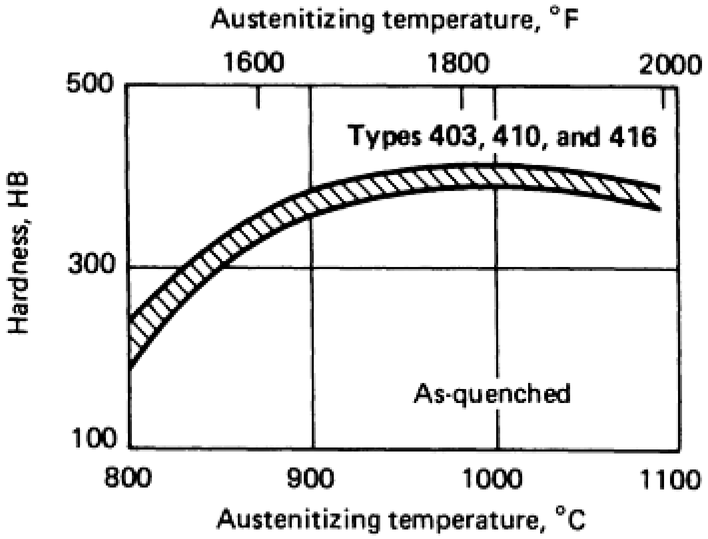

Fig. 5 Effect of austenitizing temperature on asquenched hardness. Specimens were wrought martensitic

stainless steels containing 0.15% max C.

Certain anomalies in these steels that should be considered before specifying a heat-treating procedure are exemplified in the opposing injurious effects of the high and low extremes of austenitizing temperature, depending on the subsequent tempering temperature. Table 11 shows that the Izod impact properties of type 431 are caused by retained austenite.

Table 11 Izod impact energy of wrought martensitic stainless steels using selected heat treatments

Temperature				**Izod impact energy**	
Austenitizing		**Tempering**			
°C	**°F**	**°C**	**°F**	**J**	**ft · lbf**
980	1795	315	600	20.3-33.9	15.0-25.0
1065	1950	315	600	40.7-81.3	30.0-60.0
980	1795	595	1100	74.6-108.5	55.0-80.0

Soaking times employed in the hardening of martensitic stainless steels represent a compromise between achieving maximum solution of chromium-iron carbides for maximum strength and corrosion resistance, and avoiding decarburization, excessive grain growth, retained austenite, brittleness, and quench cracking. For sections 13 mm ($\frac{1}{2}$ in.) thick and under, a soaking time of 30 to 60 min is sometimes recommended. For most parts, adding 30 min for each additional inch of thickness or fraction thereof has proved adequate. However, soaking times should be doubled if parts to be hardened have been fully annealed or isothermally annealed.

The effect of soaking time at austenitizing temperature and other variables, on the impact strength and room-temperature hardness of types 403, 420, and 431 is plotted in Fig. 6, 7, and 8.

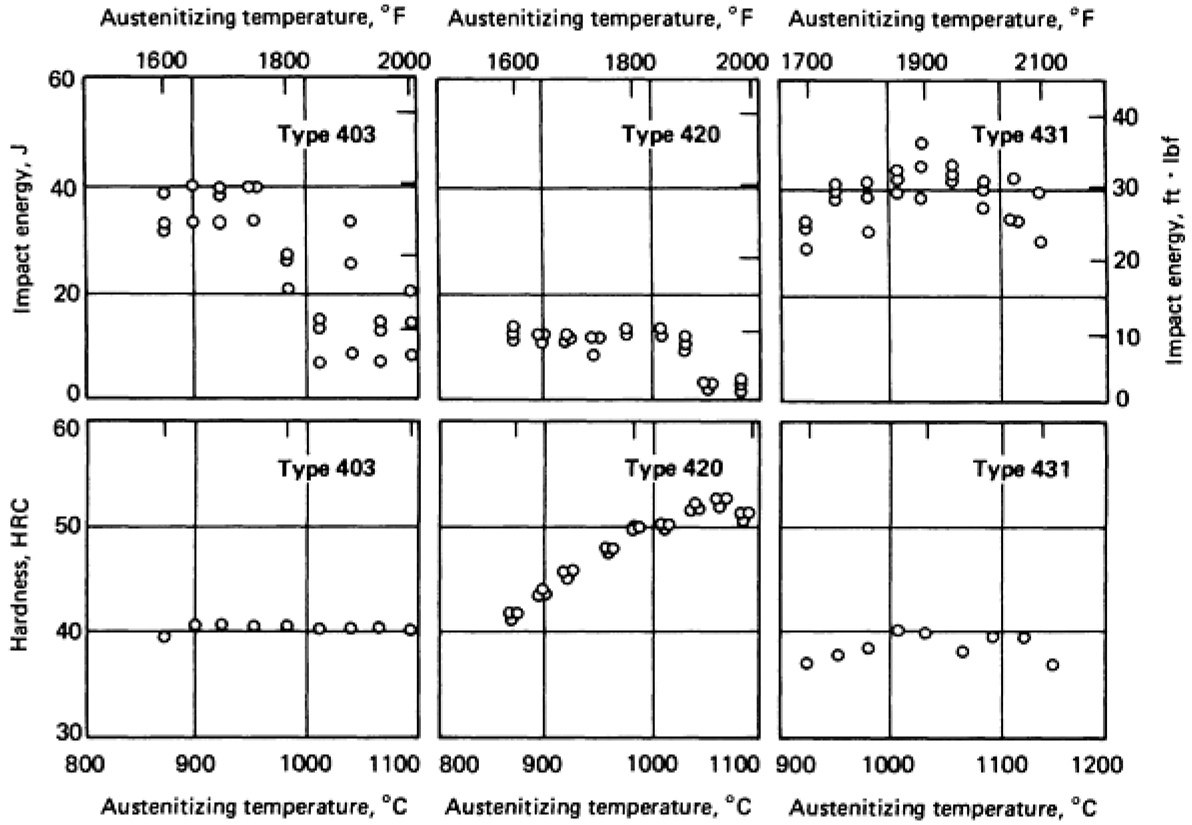

Fig. 6 Effect of variations in austenitizing temperature on hardness and impact strength of wrought martensitic stainless steels. Specimens were tempered at 480 °C (900 °F) for 4 h.

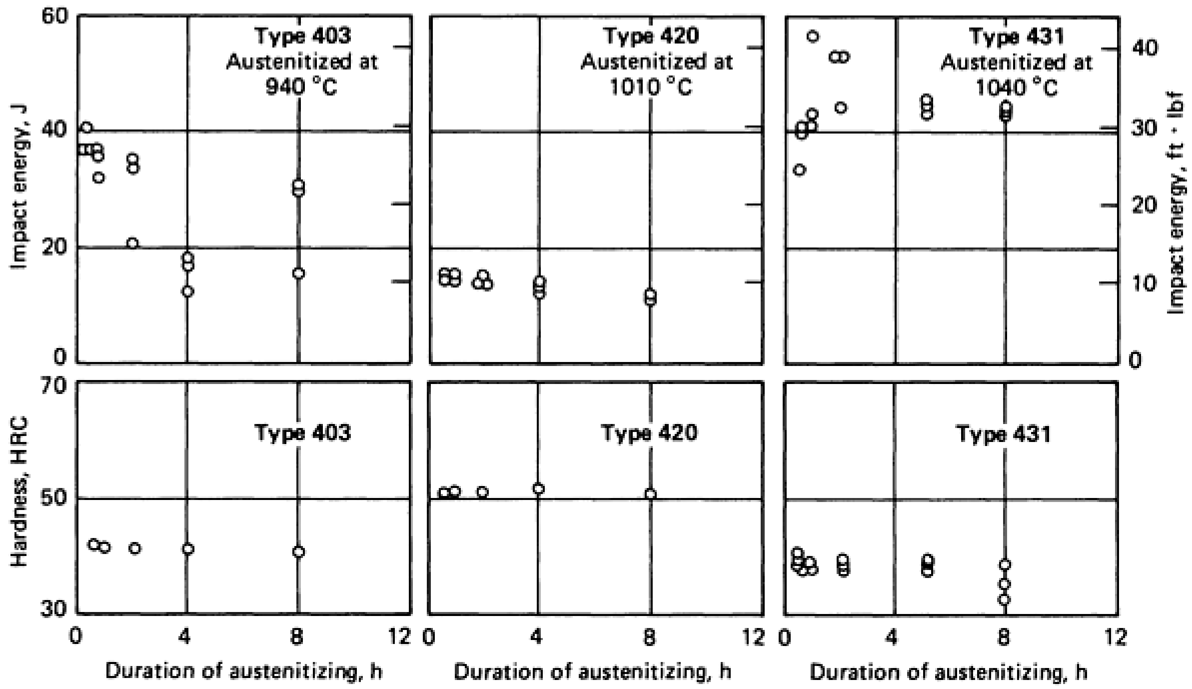

Fig. 7 Effect of variations in austenitizing time on hardness and impact strengths of wrought martensitic stainless steels. Specimens were tempered at 480 °C (900 °F) for 4 h.

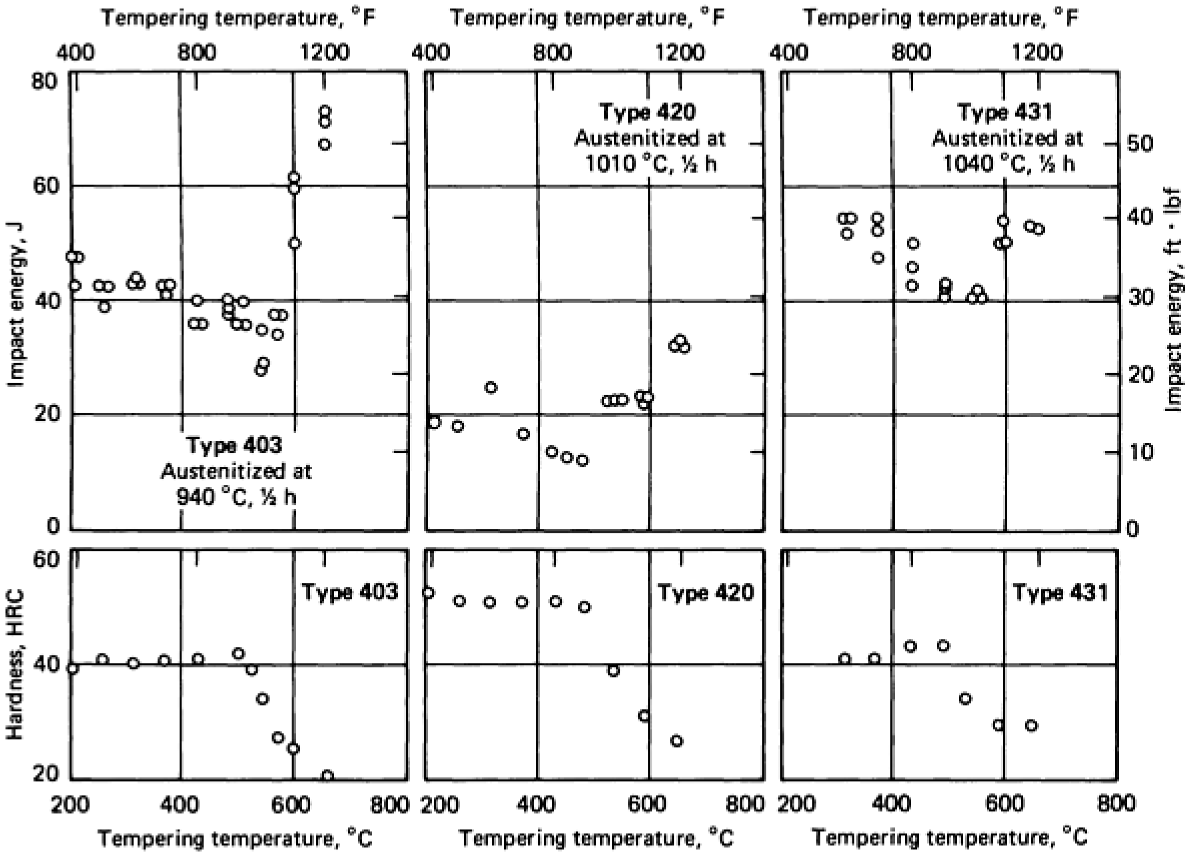

Fig. 8 Effect of variation in tempering temperature on hardness and impact strengths of wrought martensitic stainless steels

Quenching. Because of their high hardenability, martensitic stainless steels can be quenched in either oil or air. Some decrease in corrosion resistance and ductility, resulting from air quenching, may occur in these grades. These steels may precipitate carbides in grain-boundary areas if heavy sections are cooled slowly through the temperature range of about 870 to 540 °C (1600 to 1000 °F). Too slow a cooling rate in bright annealing (see the section "Austenitic Stainless Steels" in this article) these alloys may impair their corrosion resistance. Although oil quenching is preferred, air cooling may be required for large or complex sections to prevent distortion or quench cracking.

Martempering is particularly easy with these steels because of their high hardenability.

Retained Austenite. The higher-carbon martensitic grades, such as 440C, and the higher-nickel type 431, are likely to retain large amounts of untransformed austenite in the as-quenched structure, frequently as much as 30% by volume. Stress relieving at about 150 °C (300 °F) has little effect. Delayed transformation, particularly in type 440C, may occur as a result of temperature fluctuations in service, thus resulting in embrittlement and unacceptable dimensional changes.

Subzero Cooling. A portion of the austenite retained in quenching may be transformed by subzero cooling to about -75 °C (-100 °F) immediately after quenching. To obtain maximum transformation of retained austenite, double tempering may be necessary. Parts should be air cooled to room temperature between the tempering cycles.

Subzero cooling is frequently included in the hardening treatment of parts such as the slides and sleeves of slide valves, and bearings requiring maximum dimensional stability.

Reheating. For fully hardened steels, increasing degrees of recovery are achieved by:

- *Stress relieving* at 150 to 370 °C (300 to 700 °F) after hardening to reduce transformation stresses without significantly affecting microconstituents or mechanical properties

- *Tempering* at intermediate temperatures to modify properties
- *Subcritical annealing* (variously called process, mill, or low annealing) in the upper portion of the ferritic range, just below the lower critical Ac_1 temperature, to achieve maximum softening without the complications of reentering the γ or austenitic field
- *Full annealing* for maximum softening by a return to the austenitic range, followed by slow cooling

Although the strength, elongation, and hardness curves shown in Fig. 9, 10, 11, 12, 13, and 14 appear to have the same general form as those of low-alloy steel, the increase in tensile strength and hardness between 400 and 510 °C (750 and 950 °F) may be associated with a serious decrease in notch toughness, whereas tempering on the high side of the temperature range generally coincides with a decrease in corrosion resistance. The tempering temperatures most frequently employed to achieve desired hardness and other mechanical properties are included in Table 10.

(b)

Fig. 14 Effect of austenitizing and tempering temperatures on typical mechanical properties of type 440C martensitic stainless steel. Austenitized 1 h at 925 °C (1700 °F) and 2 h at 1040 °C (1900 °F); oil quenched to 65 to 95 °C (150 to 200 °F); double stress relieved at 175 °C (350 °F) for 15 min and water quenched; tempered 2 h. (a) Quenched from 925 °C (1700 °F). (b) Quenched from 1040 °C (1900 °F)

The Izod impact curves in Fig. 9, 10, 11, 12, 13, and 14 reveal a loss of impact strength when parts are tempered within the range of 370 to 650 °C (700 to 1200 °F). Tempering within this range also results in decreased corrosion resistance, particularly resistance to stress-corrosion cracking (Fig. 15). Double tempering (cooling parts to room temperature after the first tempering treatment) also is beneficial for resistance to stress corrosion.

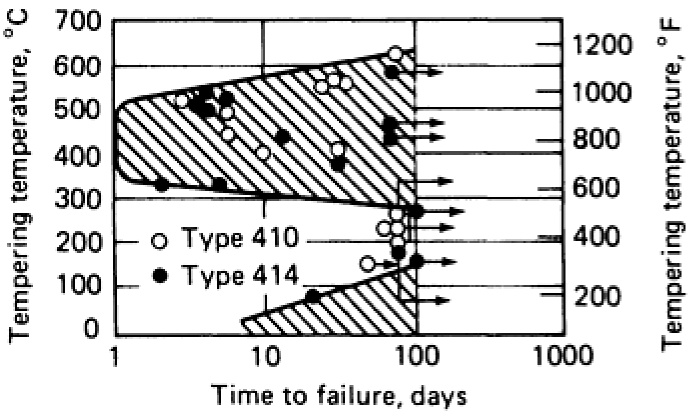

Fig. 15 Effect of tempering temperature on the stress-corrosion characteristics of two wrought martensitic stainless steels at high stress. Data apply to a stress level of 350 MPa (80 ksi) for tests in a salt fog cabinet.

Annealing. Temperatures and resulting hardnesses for process (subcritical) annealing, full annealing, and isothermal annealing are given in Table 12.

Table 12 Annealing temperatures and procedures for wrought martensitic stainless steels

Type	Process (subcritical) annealing			Full annealing			Isothermal annealing[c]	
	Temperature[a]		Hardness	Temperature[b][c]		Hardness		
	°C	°F		°C	°F		Procedure[d] °C (°F)	Hardness
403, 410	650-760	1200-1400	86-92 HRB	830-885	1525-1625	75-85 HRB	Heat to 830-885 (1525-1625); hold 6 h at 705 (1300)	**85 HRB**
414	650-730	1200-1345	99 HRB-24 HRC		Not recommended		**Not recommended**	
416, 416Se	650-760	1200-1345	86-92 HRB	830-885	1525-1625	75-85 HRB	Heat to 830-885 (1525-1625); hold 2 h at 720 (1330)	**85 HRB**
420	675-	1245-	94-97 HRB	830-	1525-	86-95 HRB	Heat to 830-885 (1525-1625);	**95 HRB**

	760	1400		885	1625		hold 2 h at 705 (1300)

440A	675-760	1245-1400	90 HRC-22 HRC	845-900	1555-1650	94-98 HRB	Heat to 845-900 (1555-1650); hold 4 h at 690	**98 HRB**
440B	675-760	1245-1400	98 HRB-23 HRC	845-900	1555-1650	95 HRB-20 HRC	Same as 440A	**20 HRC**
440C, 440F	**675-760**	**1245-1400**	**98 HRB-23 HRC**	**845-900**	**1555-1650**	**98 HRB-25 HRC**	**Same as 440A**	**25 HRC**

(a) Air cool from temperature; maximum softness is obtained by heating to temperature at high end of range.

(b) Soak thoroughly at temperature within range indicated; furnace cool to 790 °C (1455 °F); continue cooling at 15 to 25 °C/h (27 to 45 °F/h) to 595 °C (1100 °F); air cool to room temperature.

(c) Recommended for applications in which full advantage may be taken of the rapid cooling to the transformation temperature and from it to room temperature.

(d) Preheating to a temperature within the process annealing range is recommended for thin-gage parts, heavy sections, previously hardened parts, parts with extreme variations in section or with sharp reentrant angles, and parts that have been straightened or heavily ground or machined to avoid cracking and minimize distortion, particularly for types 420 and 431, and 440A, B, C, and F.

Full annealing is an expensive and time-consuming treatment; it should be used only when required for subsequent severe forming. Types 414 and 431 do not respond to full or isothermal annealing procedures within a reasonable soaking period.

Isothermal annealing is recommended where maximum softening is required and adequate facilities for controlled slow cooling are not available.

Subcritical annealing is recommended for all applications that do not require maximum softness.

Full annealing, isothermal annealing, and especially repeated process annealing promote the formation of coarse carbides that take longer to dissolve at austenitizing temperatures.

Salt Baths. Many stainless steel parts are heat treated in molten salt, with excellent results. The baths usually employed consist of barium chloride with 5 to 35% sodium or potassium chloride. Alkaline-earth and other metallic oxides build up in these baths through use, but these oxides are not harmful to low-carbon stainless steels. However, if these salt baths are also to be used for hardening other alloy steels, to avoid surface decarburization it is necessary to rectify the baths with graphite to remove the metallic oxides and with methyl chloride gas to convert the alkaline-earth oxides back to chlorides. A bath treated with methyl chloride will carburize low-carbon stainless steels unless it is aged for at least 24 h before the stainless is treated in it. To avoid this problem, stainless steel parts should be heat treated in a salt bath reserved exclusively for stainless steels.

Protective Atmospheres. Argon or helium, if used as protective atmospheres, should be exceptionally dry (with a dew point below -50 °C, or -60 °F). Because they are expensive and cannot be generated, they are rarely used. Exothermic and endothermically generated gas can be used with excellent results (see the article "Furnace Atmospheres" in this Volume). These require dew-point or infrared control so as not to carburize or decarburize the stainless grade being

heat treated. Endothermic gas containing approximately 40% hydrogen can embrittle martensitic stainless steels that are oil quenched.

An exothermic gas ratio of 6.5 or 7 to 1 is satisfactory for grades of stainless containing not more than 0.15% C. For endothermic atmospheres, dew points for specific steels and austenitizing temperatures are listed in Table 13.

Table 13 Dew points of selected wrought martensitic stainless steels at various austenitizing temperatures

Alloy	**Austenitizing temperature**		Dew point	
	°C	**°F**	**°C**	°F
420	1010	1850	10-12	**50-54**
403,410, 414, 416, 431	980	1795	16-18	**61-64**

Hydrogen embrittlement can become an important concern in the martensitic grades, generally increasing with hardness and carbon content. (It is variable and less acute in ferritic steels, and is virtually unknown in the austenitic grades.)

The embrittling hydrogen may be acquired as a result of the melting process, a heat-treating atmosphere, or chemical and electrochemical processes such as pickling and electroplating.

Most heat-treating atmospheres contain hydrogen in the form of moisture, hydrocarbons, or elemental hydrogen as an atmosphere or a dissociation product. The use of pure hydrogen or dissociated ammonia for bright annealing in one plant was associated with cracking of wire coils of types 431 and 440C, although other plants have reported no similar difficulty. Nevertheless, it is possible that some loss in ductility may result from the bright annealing of any of the martensitic stainless steels.

Less severe, the use of H_2 annealing gas with a titanium- or aluminum-bearing ferritic or martensitic grade, such as type 409, can lead to H_2 pickup and a resultant loss of bend ductility as-annealed. Low-temperature soaks of 175 to 230 °C (350 to 450 °F) in air will outgas embrittled ferritic alloys. Mill specifications outlining such baking procedures do exist.

Embrittlement has been found in oil-quenched types 403, 410, 414, and 431. Air quenching or the subsequent tempering of oil-quenched material releases the entrapped hydrogen, and ductility is restored. If a green oxide appears on the oil-quenched alloy, this must be removed prior to tempering or it will interfere with the release of entrapped hydrogen.

Additional information is available in the article "Embrittlement of Steels" in *Properties and Selection: Irons, Steels, and High-Performance Alloys,* Volume 1 of *ASM Handbook*, formerly 10th Edition *Metals Handbook.*

Precipitation-Hardening Stainless Steels

In the heat treating of precipitation-hardening (PH) stainless steels, areas of primary interest include:

- Cleaning prior to heat treatment
- Furnace atmospheres
- Time-temperature cycles
- Effect of variations in cycles

- Scale removal after heat treatment

Prior Cleaning. All parts must be cleaned thoroughly prior to heat treating. Because the chemical composition of these steels is delicately balanced, failure to remove drawing lubricants, cutting oils, and grease can lead to surface carburization and improper response to heat treatment. As a secondary benefit, thorough cleaning promotes the formation of a uniform surface scale that is readily removable.

The recommended cleaning procedure comprises vapor degreasing or solvent cleaning, followed by mechanical scrubbing with a mild abrasive alkaline cleaner to remove insoluble soils. All traces of cleaners should be removed by thoroughly rinsing with warm water.

Wet or dry abrasive blasting may be substituted for the above procedures. Recommended grits and operating details for blasting are given in Table 14. After blasting, all traces of abrasive must be removed from the work by scrubbing thoroughly.

Table 14 Recommended conditions for abrasive blast cleaning of precipitation-hardening stainless steels prior to heat treatment. All abrasives must be removed by thorough scrubbing.

Abrasive		Nozzle			Air pressure		Cleaning speed	
		Size		Angle, °				
Material	Grit No.	mm	in.		kPa	psi	mm^2/s	$in.^2/min$
Alumina (dry)	30	6.4	$\frac{1}{4}$	45-60	170-655[(a)]	25-95[(a)]	130-215	**12-20**
Garnet or alumina (dry)	36	9.5	$\frac{3}{8}$	60	240	35	645	**60**

(a) Depending on metal thickness

In some applications, cleaning prior to heat treating may be accomplished by closely controlled pickling in a 10% HNO_3-2% HF aqueous solution at 45 to 60 °C (110 to 140 °F). Time should be limited to 2 or 3 min. This method is not recommended for cleaning severely formed or previously heat-treated parts. Proprietary inhibited scale-removal preparations are available.

Furnaces fired with oil or natural gas are not entirely satisfactory for the heat treatment of these steels where finished surfaces are not to be subsequently machined. In such units, it is difficult to control combustion contaminants and to eliminate flame impingement on the parts being treated. Electric furnaces or gas-fired radiant-tube furnaces are generally used for heat treating precipitation-hardening stainless steels.

Furnace Atmospheres. Air is a satisfactory furnace atmosphere for austenite-conditioning and annealing operations. Controlled reducing atmospheres, such as dissociated ammonia or bright-annealing gas, introduce the potential hazard of nitriding or carburizing, either of which has a deleterious effect on mechanical properties.

Bright annealing may be done in hydrogen, argon, or helium atmospheres, provided a dew point of -55 °C (-65 °F) or lower is maintained. The cooling rate from the annealing temperature must be approximately equal to that of cooling in still air. Austenite-conditioning treatments at temperatures as high as 925 to 955 °C (1700 to 1750 °F) may also be performed in dry hydrogen, argon, or helium, maintaining the same low dew point. A scale-free surface will be obtained.

The lower austenite-conditioning temperatures, such as 760 °C (1400 °F), present difficulties in achieving scale-free surfaces in dry hydrogen, argon, or helium. An air atmosphere is generally used at these temperatures. For complete freedom from scale or discoloration at the lower temperatures, a vacuum furnace is required.

Final hardening of these steels is performed at relatively low temperatures, and an air atmosphere is acceptable for these treatments.

Heat-Treating Procedures. Recommended procedures for full annealing, austenite conditioning, transformation cooling, and age tempering (precipitation hardening) are given in Table 15.

Table 15 Recommended heat-treating procedures for semiaustenitic precipitation-hardenable stainless steels

UNS S17400

Homogenization. 1175 ± 15 °C (2150 ± 25 °F) for 2 h + 30 min per 25 mm (1 in.) [(a)]

Austenite conditioning (solution treatment). 1040 ± 15 °C (1900 ± 25 °F) for 30 min + 30 min per 25 mm (1 in.) [(a)]

Transformation cooling. To below +30 °C (+90 °F)

Precipitation hardening. To obtain minimum tensile strengths shown, use the following treatments for wrought alloys [(b)] :

MPa	**ksi**	**°C**	**°F**	h
1310	190	480 ± 5	(900 ± 10)	**1**
1170	170	495 ± 5	(925 ± 10)	**4**
1070	155	555 ± 5	(1030 ± 10)	**4**
1030	150	565 ± 5	(1050 ± 10)	**4**
1000	145	580 ± 5	(1075 ± 10)	**4**
930	**135**	**620 ± 5**	**(1150 ± 10)**	4

Comparable treatments for cast materials [(b)] :

MPa	**ksi**	**°C**	**°F**	h
1240	180	480 ± 5	(900 ± 10)	**4**
1170	170	495 ± 5	(925 ± 10)	**4**

1035	150	540 ± 5	(1000 ± 10)	**4**
895	**130**	**595 ± 5**	**(1100 ± 10)**	**4**

UNS S17700

Solution annealing. 1065 ± 15 °C (1950 ± 25 °F) for 3 min + 1 min per 0.25 mm (0.01 in.); air cool

RH treatments

Austenite conditioning. 955 ± 15 °C (1750 ± 25 °F) for 10 rain + 1 min per 0.25 mm (0.01 in.); air cool [(c)]

Transformation cooling. To below -70 °C (-90 °F) for 8 h

Precipitation hardening. To obtain minimum tensile strengths shown, the following treatments are recommended [(b)] :

MPa	**ksi**	**°C**	**°F**	h
1450	210	510 ± 5	(950 ± 10)	**1**
1240	180	565 ± 5	(1050 ± 10)	**1**

1310	**190**	**565 ± 5**	**(1050 ± 10)**	**1**

TH treatments

Austenite conditioning. 760 ± 15 °C (1400 ± 25 °F') for 1 $\frac{1}{2}$ h; cool within 1 h to below 15 °C (60 °F) but above 0 °C (32 °F), and hold at least $\frac{1}{2}$ h before precipitation hardening

Precipitation hardening. For minimum tensile strength of 1310 MPa (190 ksi) [(b)] : 565 ± 5 °C (1050 ± 10 °F) for 1 $\frac{1}{2}$ h

UNS S35000

Solution annealing. Wrought materials only: 1065 ± 15 °C (1950 ± 25 °F) for 3 min + 1 min per 0.25 mm (0.01 in.); air cool

Austenite conditioning. 930 ± 5 °C (1710 ± 10 °F) for 10 min + 1 min per 0.25 mm (0.01 in.); air cool [(c)]

Transformation cooling. To -75 ± 5 °C (-100 ± 10 °F) for 3 h (minimum)

Precipitation hardening. To obtain minimum tensile strengths shown, the following treatments are recommended [(b)] :

MPa	**ksi**	**°C**	**°F**	h
1275	185	455 ± 5	(850 ± 10)	**3**
1170	170	510 ± 5	(950 ± 10)	**3**
1140	**165**	**540 ± 5**	**(1000 ± 10)**	**3**

UNS S35500

Homogenization. Castings only: 1095 ± 15 °C (2000 ± 25 °F) for 2 h; air cool (water quench sections over 50 mm, or 2 in.). Bar and

forgings: 1050 ± 15 °C (1925 ± 25 °F) for 1 to 3 h; water quench. Cool all forms to below -70 °C (-90 °F) and hold 3 h minimum.

Solution annealing. 1025 ± 15 °C (1875 ± 25 °F) for 1 h per 25 mm (1 in.); water quench

Machinability treatment. 760 ± 15 °C (1400 ± 25 °F) for 3 h; air cool. Refrigerate to -70 °C (-90 °F) and hold for 3 h. Reheat to 565 ± 15 °C (1050 ± 25 °F) for 3 h.

For -70 °C (-90 °F) transformation:

Austenite conditioning. Castings: 980 ± 15 °C (1800 ± 25 °F) for 2 h; air cool (oil quench sections over 3 mm, or 0.125 in.). Wrought materials: 930 ± 15 °C (1710 ± 25 °F) for 15 min per in.; air cool (oil quench sections over 3 mm, or 0.125 in.)

Transformation cooling. To -75 ± 5 °C (-100 ± 10 °F) for 3 h

Precipitation hardening. To obtain minimum tensile strengths shown, use the following treatments for wrought alloys [b] :

MPa	**ksi**	**°C**	**°F**	h
1310	190	455 ± 5	(850 ± 10)	**3**
1170	**170**	**540 ± 5**	**(1000 ± 10)**	**3**

For castings, to obtain minimum tensile strength of 1240 MPa (180 ksi) [b] : 455 ± 5 °C (850 ± 10 °F) for 2 h

UNS S45000

Solution annealing. 1040 ± 15 °C (1900 ± 25 °F) for 1 h at heat [d] , water quench

Precipitation hardening. Typical tensile strengths shown may be obtained by the following treatments:

MPa	**ksi**	**°C**	**°F**	h
1345	195	480 ± 5	(900 ± 10)	**4, air cool**
1170	170	540 ± 5	(1000 ± 10)	**4, air cool**

H1150M condition (after annealing). 760 ± 8 °C (1400 ± 15 °F) for 2 h, air cool + 620 ± 5 °C (1150 ± 10 °F) for 4 h, air cool

Typical tensile strength. 860 MPa (125 ksi)

UNS S13800

Solution annealing. 925 ± 8 °C (1700 ± 15 °F) for 1 h [(d)] , air cool or oil quench

Precipitation hardening. Typical tensile strengths shown may be obtained by the following treatments:

MPa	**ksi**	**°C**	**°F**	h
1550	225	510 ± 5	(950 ± 10)	**4, air cool**
1310	190	565 ± 5	(1050 ± 10)	**4, air cool**
1000	**145**	**620 ± 5**	**(1150 ± 10)**	**4, air cool**

H1150M condition (after annealing). 760 ± 8 °C (1400 ± 15 °F) for 2 h, air cool + 620 ± 5 °C (1150 ± 10 °F) for 4 h, air cool

Typical tensile strength. 895 MPa (130 ksi)

(a) To prevent cracking and ensure uniform properties, cool as follows: 75 mm (3 in.) and less, oil quench or air cool; 75 to 150 mm (3 to 6 in.), air cool; 150 mm (6 in.) and over, air cool under cover. *All parts must be cooled to below 30 °C (90 °F)* prior to the precipitation-hardening cycle.

(b) If hardness exceeds maximum specified, reheat treat at a slightly higher temperature for a minimum of 30 min.

(c) Air cool to room temperature; *do not reheat before transformation cooling.*

(d) Time at heat is dependent upon section size. Normally, a 1 h hold at temperature is suggested.

17-4 PH (UNS S17400) is a precipitation-hardening steel that has an essentially martensitic structure and limited formability when supplied in the solution-treated condition. Fabrication is followed by hardening in the range of 480 to 620 °C (900 to 1150 °F) (Table 15).

Care should be taken in using this alloy in the solution-treated condition because in this condition its ductility can be relatively low. Hardening to any of the strength levels shown in Table 15 improves toughness.

17-7 PH (UNS S17700) is normally supplied in the solution-annealed condition (condition A), in which it is soft and formable. Heat treatment is accomplished through the use of the transformation-hardened (TH) or refrigeration-hardened (RH) procedures indicated in Table 15. The choice of method of heat treatment is usually dictated by the ease with which the particular sequence fits into the production techniques of the user. Parts that receive significant deformation should be heat treated to RH 950, or soft spots may result.

This alloy is also supplied in the cold-rolled condition (condition C). Here, transformation has been achieved by cold rolling, and heat treatment is reduced to a single step: 480 °C (900 °F) for 1 h. Although strength and stress-corrosion resistance are greatly increased by this treatment, ductility is reduced and formability is limited.

PH 15-7 Mo (UNS S15700) is a high-strength modification of 17-7 PH. It is supplied in the same condition as 17-7 PH and requires identical heat-treating procedures. Table 15 illustrates the strength levels obtainable with PH 15-7 Mo.

15-5 Ni alloys (UNS S15500) are normally supplied in the solution-treated condition. As with 17-4 PH, care should be used in applying the material in the solution-treated condition. The alloy can be hardened by heating to a temperature in the range of 480 to 620 °C (900 to 1150 °F) for 1 to 4 h, depending on the temperature, and then air cooling. Table 15 illustrates typical strength levels versus hardening procedures.

13-8 Mo alloys (UNS S13800) are normally supplied in the solution-treated condition. They can be hardened to high strength levels by a single low-temperature treatment. Table 15 illustrates typical strength levels versus hardening procedures.

AM-350 and Pyromet 350 (UNS S35000) are normally purchased in the solution-treated condition; however, after severe forming or cold working, it may require a second annealing treatment. The annealing temperature limits, indicated in Table 15, are critical. High temperatures reduce strength; lower temperatures adversely affect formability.

After annealing and conditioning at 930 °C (1710 °F), AM-350 is usually subzero cooled, and then aged at 455 °C (850 °F) for 3 h; this treatment produces maximum strength. Maximum toughness is achieved by aging in the range of 480 to 540 °C (900 to 1000 °F). The recommended temperature for subzero cooling must be carefully observed. Cooling to much lower temperatures, such as -195 °C (-320 °F), results in incomplete transformation, as does failure to hold at the recommended temperature for at least 3 h.

AM-355 and Pyromet 355 (UNS S35500) flat products are supplied in either the solution-treated or solution-treated and cold-rolled condition, whereas bar products are usually supplied in the equalized and over-tempered condition for best machinability. Most castings are supplied in the as-cast condition.

Although, as indicated in Table 15, the homogenizing and austenite-conditioning treatments applied to castings differ from those applied to wrought materials (higher temperatures being used for castings in both treatments), subzero cooling is required for all forms to obtain maximum toughness and corrosion resistance. The full annealing treatment shown in Table 15 would normally be applicable only to flat products. The machinability treatment is required for obtaining good machining characteristics in this alloy.

Wrought materials should be aged at 455 °C (850 °F) for maximum strength, and at 540 °C (1000 °F) for maximum ductility and toughness. The usual aging treatment for castings consists of holding at 455 °C (850 °F) for 2 h.

Custom 450 (UNS S45000) stainless is normally supplied in the solution-treated condition, requiring no further heat treatment for many applications. It is easily fabricated in the annealed condition. A single-step hardening treatment develops higher strength with good ductility and toughness.

The recommended minimum hardening temperature of 480 °C (900 °F) produces the optimum combination of strength, ductility, and toughness. Hardening at temperatures up to 620 °C (1150 °F) increases the ductility and decreases strength (Table 15).

Custom 455 (UNS S45500) stainless is normally in the annealed condition. It is relatively soft and easily formable in the annealed condition. A single-step hardening treatment develops exceptionally high yield strengths with good ductility and toughness. Harden by heating in the range of 480 to 565 °C (900 to 1050 °F). See Table 15.

Variations in Heat-Treating Cycles. One of the principal advantages of these materials is their versatility. Although certain heat treatments have been classified as standard, there are applications where deviations from these standards are desirable. The series of curves in Fig. 16, 17, 18, 19, and 20 shows how these deviations affect mechanical properties.

in.) in diameter from four heats.

Scale Removal after Heat Treating. The amount and nature of scale vary with the degree of cleanness of the work being treated, the furnace atmosphere, and the temperature and duration of heat treatment. In the following discussion, it will be assumed that all heat-treating operations are performed in an air atmosphere. A variety of descaling methods may be employed; the choice depends on the type of steel and the facilities available.

In removing scale formed during homogenization or full annealing, the use of a 10% HNO_3-2% HF aqueous solution at 45 to 60 °C (110 to 140 °F) has been effective. Exposure to the acid solution should be limited to a period of 3 min. Removal of loosened scale may be facilitated by the use of high-pressure water or steam. A uniform surface is evidence of a well-cleaned part. The use of molten salts to condition the scale is limited because the temperature involved (about 450 °C, or 850 °F) can age harden any martensite in the microstructure.

The austenite-conditioning treatments produce a scale that is best removed by mechanical means. Acids should be avoided because they are a possible source of intergranular attack. Wet grit-blasting processes have been widely used to remove these scales and have been found to be highly satisfactory.

The final step in heat treating (precipitation hardening) produces a discoloration of heat tint. It is desirable to use mechanical means to remove this oxide from 17-7 PH, PH 15-7 Mo, AM-350, and AM-355. The HNO_3-HF solution has been used on these steels, but extreme care is required to prevent intergranular attack. The acid solution may be used satisfactorily with 17-4 PH. To a lesser extent, electropolishing has also been used to remove the final heat tint resulting from precipitation hardening. Also available are proprietary cleaners that have been successful in removing the heat tint discoloration.

Stainless Steel Castings

The heat treatment of stainless steel castings follows closely in purpose and procedure the thermal processing of comparable wrought materials. However, the differences in detail warrant separate consideration here.

Because they are not cold worked or cold formed, castings of the older, conventional martensitic grades CA-15 and CA-40 (UNS J91150 and J91153) do not require subcritical annealing to remove the effects of cold working. However, in work-hardenable ferritic alloys, machining and grinding stresses are relieved at temperatures from about 260 to 540 °C (500 to 1000 °F). Casting stresses in the martensitic castings noted above should be relieved by subcritical annealing prior to further heat treatment. When these hardened martensitic castings are stress relieved, the stress-relieving temperature must be kept below the final tempering or aging temperature.

An improved, cast martensitic alloy, CA-6NM (UNS J91540), possesses better casting behavior, improved weldability, and equals or exceeds all of the mechanical, corrosion, and cavitation resistance properties of CA-15, and, as a result, has largely replaced the older alloy. Both CA-6NM and CA-15 castings are usually supplied in the normalized condition at 955 °C (1750 °F) minimum and tempered at 595 °C (1100 °F) minimum. However, when it is necessary or desirable to anneal CA-6NM castings, a temperature of 790 to 815 °C (1450 to 1500 °F) should be used. The alloy should be furnace cooled or otherwise slow cooled to 595 °C (1100 °F), after which it may be cooled in air. When stress relieving is required, CA-6NM may be heated to 620 °C (1150 °F) maximum and followed by slow cooling to prevent the formation of martensite.

Homogenization

Alloy segregation and dendritic structures may occur in castings and may be particularly pronounced in heavy sections. Because castings are not subjected to the high-temperature mechanical reduction and soaking treatments entailed in the mill processing of wrought alloys, it is frequently necessary to homogenize some alloys at temperatures above 1095 °C (2000 °F) to promote uniformity of chemical composition and microstructure. Full annealing of martensitic castings results in recrystallization and maximum softness, but it is less effective than homogenization in eliminating segregation. Homogenization is a common procedure in the heat treatment of precipitation-hardening castings.

Ferritic and Austenitic Alloys

The ferritic, austenitic, and mixed ferritic-austenitic alloys are not hardenable by heat treatment. They can be heat treated to improve their corrosion resistance and machining characteristics. The ferritic alloys CB-30 and CC-50 (UNS J91803 and J92615) are annealed to relieve stresses and reduce hardness by being heated above 790 °C (1450 °F) (Table 16).

Table 16 Annealing of ferritic and austenitic stainless steel castings

Type	**Minimum temperature**		**Quench**[(a)]	Typical ultimate tensile strength[(b)]	
	°C	**°F**		**MPa**	ksi
For full softness

(a) FC, furnace cool; W, water; O, oil; A, air.

(b) Approximate.

(c) Furnace cool to 540 °C (1000 °F), and then air cool.

(d) CF-8C may be reheated to 870 to 925 °C (1600 to 1700 °F), and then air cooled, for precipitation of niobium carbides.

(e) CF-12M should be quenched from a temperature above 1095 °C (2000 °F).

Solution Annealing. The austenitic alloys achieve maximum resistance to intergranular corrosion by the high-temperature heating and quenching procedure known as solution annealing (Table 16). As-cast structures, or castings exposed to temperatures in the range from 425 to 870 °C (800 to 1600 °F), may contain complex chromium carbides precipitated preferentially along grain boundaries in wholly austenitic alloys. This microstructure is susceptible to intergranular corrosion, especially in oxidizing solutions. (In partially ferritic alloys, carbides tend to precipitate in the discontinuous ferrite pools; thus, these alloys are less susceptible to intergranular attack.) The purpose of solution annealing is to ensure complete solution of carbides in the matrix and to retain these carbides in solid solution.

Solution-annealing procedures for all austenitic alloys are similar, and consist of heating to a temperature of about 1095 °C (2000 °F), holding for a time sufficient to accomplish complete solution of carbides, and quenching at a rate fast enough to prevent reprecipitation of the carbides--particularly while cooling through the range from 870 to 540 °C (1600 to 1000 °F). Temperatures to which castings should be heated prior to quenching vary somewhat, depending on the alloy (Table 16).

Stabilizing Treatment. As shown in Table 16, a two-step heat-treating procedure may be applied to the niobium-containing CF-8C (UNS J92710) alloy. The first treatment consists of solution annealing. This is followed by a stabilizing treatment at 870 to 925 °C (1600 to 1700 °F), which precipitates niobium carbides, prevents formation of the damaging chromium carbides, and provides maximum resistance to intergranular attack.

Because of their low carbon contents, CF-3 and CF-3M (UNS J92700 and J92800) as-cast do not contain enough chromium carbides to cause selective intergranular attack, and hence may be used in some corrodents in this condition; for maximum corrosion resistance, however, these grades require solution annealing.

Martensitic Alloys

Castings of the CA-6NM composition should be hardened by air cooling or oil quenching from a temperature of 1010 to 1065 °C (1850 to 1950 °F). Even though the carbon content of this alloy is lower than that of CA-15, this fact in itself and the addition of molybdenum and nickel enable the alloy to harden completely without significant austenite retention when cooled as suggested.

The choice of cooling medium is determined primarily by the maximum section size. Section sizes in excess of 125 mm (5 in.) will harden completely when cooled in air. CA-6NM is not prone to cracking during cooling from elevated temperatures. For this reason, no problem should arise in the air cooling or oil quenching of configurations that include thick as well as thin sections.

A wide choice of mechanical properties is available through the choice of tempering temperature. Castings of CA-6NM are normally supplied normalized and tempered at 595 to 620 °C (1100 to 1150 °F). Reaustenitizing occurs upon tempering above 620 °C (1150 °F), the amount of reaustenitization increasing with increasing temperature. Depending on the amount of this transformation, cooling from such tempering temperatures may adversely affect both ductility and toughness through the transformation to untempered martensite.

Even though the alloy is characterized by a decrease in impact strength when tempered in the range of 370 to 595 °C (700 to 1100 °F), the minimum reached is significantly higher than that of CA-15. This improvement in impact toughness results from the presence of molybdenum and nickel in the composition and from the lower carbon content. The best combination of strength with toughness is obtained when the alloy is tempered above 510 °C (950 °F).

Figure 21 describes the effect of tempering temperature on the hardness, strength, ductility, and toughness properties of CA-6NM and illustrates that strengths even higher than those considered typical can be obtained by tempering at lower temperatures without a disturbing loss of ductility or toughness.

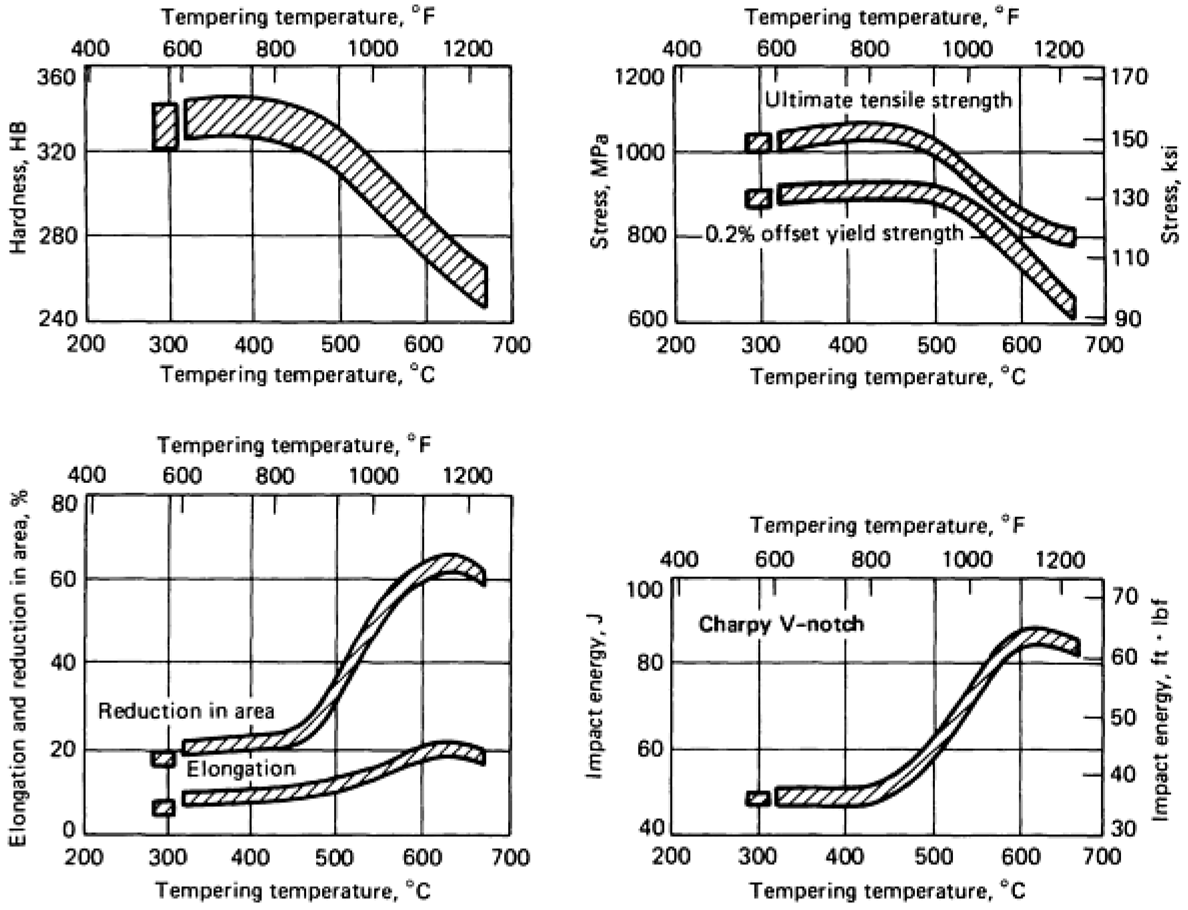

Fig. 21 Effect of tempering temperature on the mechanical properties of a CA-6NM standard keel block. Courtesy of ESCO Corporation

The minor loss of toughness and ductility that does occur is associated with the lesser degree of tempering that takes place at the lower temperature and not with embrittlement, as might be the situation with other 12% Cr steels that contain no molybdenum. The addition of molybdenum to 12% Cr steels makes them unusually stable thermally and normally not susceptible to embrittlement in the annealed or annealed and cold-worked conditions, even when exposed for long periods at 370 to 480 °C (700 to 900 °F). There are no data currently available on such steels in the quenched and tempered or normalized and tempered conditions.

Another significant practical advantage of CA-6NM is its relative freedom from the rapid drop in hardness when tempered above about 510 °C (950 °F). Figure 22 shows clearly that a given increase in tempering temperature produces a much more gradual decrease in hardness as compared with CA-15. This makes heat treating much easier and cheaper and decreases the frequency of rejects and/or the necessity for reheat treatment.

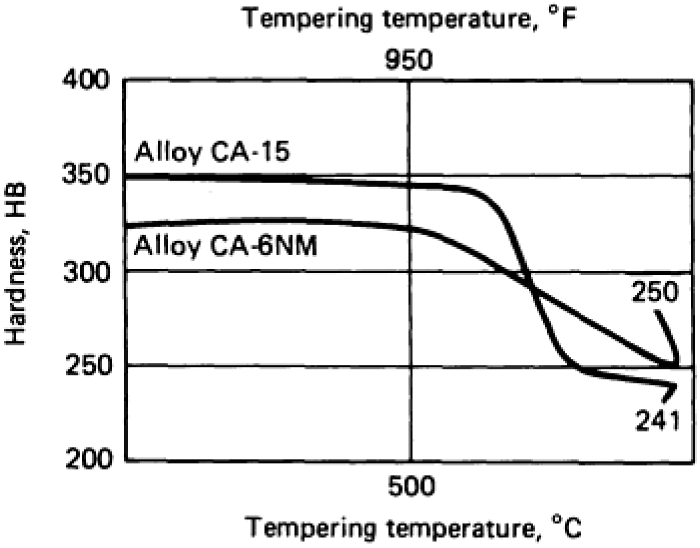

Fig. 22 Influence of tempering temperature on the hardness of CA-6NM and CA-15. Courtesy of ESCO Corporation

The hardening procedures for CA-15 castings are similar to those used for the comparable wrought alloy (type 410). Austenitizing consists of heating to 955 to 1010 °C (1750 to 1850 °F) and soaking for a minimum of 30 min; the high side of this temperature range is normally employed. Parts are then cooled in air or quenched in oil. To reduce the probability of cracking in the brittle, untempered martensitic condition, tempering should take place immediately after quenching.

Tempering is performed in two temperature ranges: up to 370 °C (700 °F) for maximum strength and corrosion resistance, and from 595 to 760 °C (1100 to 1400 °F) for improved ductility at lower strength levels. Tempering in the range of 370 to 595 °C (700 to 1100 °F) is normally avoided because of the resultant low impact strength. Figure 23 shows the nominal mechanical properties obtained in CA-15 castings as a function of tempering temperature. Additional data on mechanical properties are given in Table 17. These data are based on several heats of shell cast CA-15 alloy. The standard heat-treating procedures for CA-15, CA-40, and CA-6NM are given in Table 18. In the hardened and tempered condition, CA-40 provides higher tensile strength and lower ductility than CA-15 tempered at the same temperature. Both alloys can be annealed by cooling slowly from the range 845 to 900 °C (1550 to 1650 °F).

Table 17 Effects of four methods of heat treatment on typical mechanical properties of cast CA-15

Specimens were taken from shell mold cast keel blocks; data indicate results obtained on four specimens treated by each method.

Heat treatment[(a)]	**Ultimate tensile strength**		**Yield strength**		**Elongation in 50 mm (2 in.), %**	Reduction in area, %
	MPa	**ksi**	**MPa**	**ksi**

(a) Annealing for maximum softness; slow furnace cool from temperature.

(b) Quench in oil or air.

(c) Approximate.

(d) Hold at temperature for a minimum of 30 min.

(e) Tempering at 370 to 595 °C (700 to 1100 °F) is not recommended because low-impact ductility results.

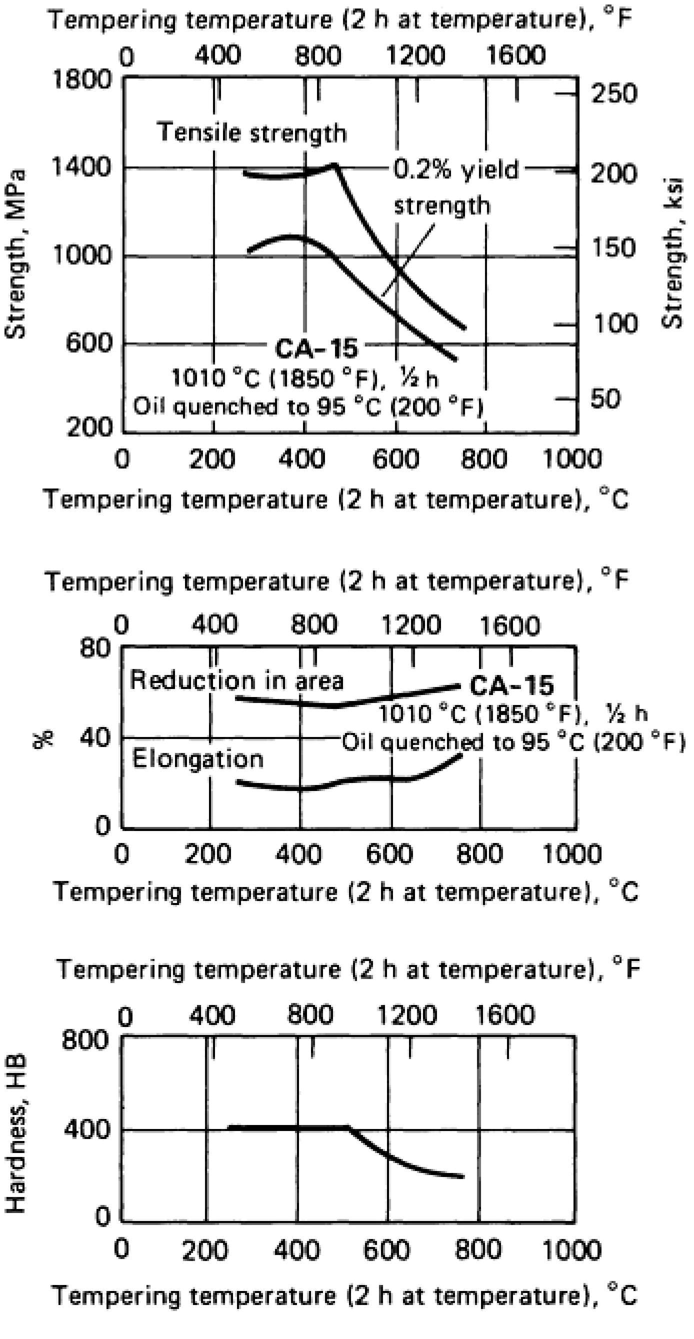

Fig. 23 Effect of tempering temperature on typical room-temperature mechanical properties of CA-15 castings

Additional information is available in the article "High-Alloy Steels," in Casting, Volume 15 of *ASM Handbook*, formerly 9th Edition *Metals Handbook.*

Precipitation-Hardening Alloys

It is desirable to subject precipitation-hardenable castings to a high-temperature homogenization treatment to reduce alloy segregation and to obtain more uniform response to subsequent heat treatment. Even investment castings that are cooled slowly from the pouring temperature exhibit more nearly uniform properties when they have been homogenized. Recommended homogenizing treatments for precipitation-hardening alloys 17-4 PH and AM-350 are included in Table 15.

17-4 PH Castings. When 17-4 PH (ASTM CB-7Cu-1 and CB-7Cu-2) is cast in plastic-bonded shell molds, the surface is carburized by decomposition of the binder. The added carbon prevents proper heat-treating response of the casting surface. Satisfactory response is obtained when surface carbon is removed prior to the homogenization treatment.

In addition to homogenization, other heat-treating procedures for 17-4 PH castings include solution annealing and precipitation hardening. Details of these procedures are given in Table 15. The preferred temperature range for precipitation hardening is 480 to 595 °C (900 to 1100 °F). The mechanical properties obtained at different aging temperatures are given in Table 19.

Table 19 Effect of temperature of 1-h aging treatment on typical properties of investment cast 17-4 PH stainless steels. Data obtained using cast test bars.

Aging temperature[(a)]		**Ultimate tensile strength**		**Yield strength, 0.2%**		**Elongation in 50 mm (2 in.), %**	Hardness, HRC

595	1100	1080	157	840	122	16	**34**
650	**1200**	**1055**	**153**	**895**	**130**	**12**	**32**

(a) Before aging, specimens were homogenized ($1\frac{1}{2}$ at 1150 °C, or 2100 °F, air cool) and solution annealed ($\frac{1}{2}$ h at 1040 °C, or 1900 °F, oil quench); subzero transformation not employed. After 1 h at aging temperature, specimens were air cooled.

The tendency of 17-4 PH castings to overage is reduced by the addition of about 0.25% combined niobium plus tantalum to the alloy. The effect of time at aging temperature on the mechanical properties of niobium-free and niobium-containing 17-4 PH investment castings are shown in Table 20.

Table 20 Effect of aging time at 480 °C (900 °F) on typical properties of investment cast 17-4 PH stainless steels[(a)]

(a) Treatment prior to aging: $1\frac{1}{2}$ h at 1150 °C (2100 °F), air cool; 1 h at 1040 °C (1900 °F), oil quench

AM-350 and AM-355. Although investment castings made of these alloys do not necessarily require a homogenizing treatment, this treatment provides a more uniform response to subsequent heat treatment. Shell mold and sand castings made of AM-355 that were extremely brittle without homogenization regained ductility after homogenizing at 1095 °C (2000 °F) for 2 h minimum. Heat-treating procedures and effects of tempering temperatures up to 650 °C (1200 °F) on mechanical properties of AM-355 shell mold castings are given in Table 21.

Table 21 Effects of tempering temperature on typical properties of shell mold cast AM-355[(a)]

Condition	Ultimate tensile strength		Yield strength[(b)]		Elongation in 50 mm (2 in.), %	Reduction in area, %
	MPa	ksi	MPa	ksi

595 (1100)	1195	173	940	136	35	**14**

(a) Treatment prior to tempering: $1\frac{1}{2}$ h at 1095 °C (2000 °F) and then furnace cool to 980 °C (1800 °F); soak at 980 °C (1800 °F) for $1\frac{1}{2}$ h and then water quench; subzero cool at -85 °C (-120 °F) for 6 h.

(b) 0.2% offset

When AM-355 castings are welded, maximum mechanical properties are obtained when the castings are fully heat treated after welding (Table 22). Heat treatments prior to welding have little effect on properties when a complete heat treatment follows welding.

Table 22 Effect of heat treating and welding sequence on typical properties of AM-355 castings

Sequence[(a)]	Ultimate tensile strength	Yield strength, 0.2%	Elongation in 50 mm (2 in.), %

Heat Treating of Superalloys

Daniel A. DeAntonio, Carpenter Technology Corporation; David Duhl, Pratt & Whitney, a Division of United Technologies Corporation; Timothy Howson, Wyman Gordon Company; Michael F. Rothman, Haynes International, Inc.

Introduction

SUPERALLOYS are heat-resistant alloys based on nickel, iron-nickel, and cobalt-nickel that exhibit a good combination of mechanical strength and resistance to surface degradation. Compositions of wrought and cast superalloys are listed in Tables 1 and 2, respectively. The high-temperature strength of all superalloys is based on the principle of a stable face-centered cubic (fcc) matrix combined with either precipitation strengthening and/or solid-solution hardening. In age-hardenable nickel-base alloys the γ' intermetallic (Ni_3Al, Ti) is generally present for strengthening, while the non-hardenable nickel-, cobalt-, and iron-base alloys rely on solid-solution strengthening of the fcc (γ) matrix. Iron-base and nickel-iron superalloys may also develop, in addition to γ', second-phase strengthening from the γ'' (Ni_3Nb) intermetallic and perhaps η(Ni_3Ti). Cobalt-base superalloys may develop some precipitation strengthening from carbides (Cr_7C_3, $M_{23}C_6$), but no intermetallic-phase strengthening equal to the γ' strengthening in nickel-base alloys has been discovered in cobalt-base superalloys.

This article describes the procedures for heat treatment of superalloys and the resulting properties. The first part briefly reviews the heat-treating processes and the special considerations required by superalloys. The later sections describe these processes for both the wrought (Table 1) and cast (Table 2) versions of the age-hardenable and solid-solution-strengthened superalloys.

Heat-Treating Operations

Stress relieving of superalloys frequently entails a compromise between maximum relief of residual stress and effects deleterious to high-temperature properties and/or corrosion resistance. True stress relieving of wrought material is usually, but not always, confined to non-age-hardenable alloys because a full-solution treatment is useful prior to age-hardening. In addition, the stress-relieving temperature would typically fall within the upper temperature range for age-hardening.

Time and temperature cycles vary considerably, depending on the metallurgical characteristics of the alloy and on the type and magnitude of the residual stresses developed in the prior fabrication processes. Stress-relieving temperatures are usually below the annealing or recrystallization temperatures.

Annealing. When applied to superalloys, annealing implies full annealing, that is, complete recrystallization and attaining maximum softness. The practice is usually applied to non-hardening wrought alloys. For most of the age-hardenable alloys, the annealing cycles are the same as for solution treating. However, the two treatments serve different purposes. Annealing is used mainly to reduce hardness and increase ductility to facilitate forming or machining, prepare for welding, relieve stresses after welding, produce specific microstructures, or soften age-hardened structures by resolution of second phases. Solution treating is intended to dissolve second phases to produce maximum corrosion resistance or to prepare for age hardening.

Most wrought superalloys can be cold formed but are more difficult to form than austenitic stainless steels. Severe cold-forming operations may require several intermediate annealing operations. Full annealing must be followed by fast cooling.

Annealing should be conducted after welding the age-hardenable alloys if highly restrained joints are involved. For alloys sensitive to strain age cracking, heating rates must be rapid. If the configuration of the weldment does not permit annealing, aging may be used for stress relieving in alloys not prone to strain age cracking.

Reheating for hot working is similar to annealing in that the aim is to promote adequate formability of the metal being deformed. Control of temperature can be critical to resultant properties, as varying degrees of recrystallization and control of grain growth may be desired. In most standard operations, heating or reheating for hot working is a full annealing step with recrystallization and dissolution of all or most secondary phases. Additional discussion of controlled heating for hot working can be found in the section "Thermomechanical Processing" in this article.

Solution Treating and Quenching. The first step in heat treating superalloys is usually solution treatment. In some wrought alloys, the solution-treating temperature will depend on the properties desired. A higher temperature is specified for optimum creep-rupture properties; a lower temperature is used for optimum short-time tensile properties at elevated temperature, improved fatigue resistance (via finer grain size), or improved resistance to notch rupture sensitivity.

The higher solution-treating temperature will result in some grain growth and more extensive dissolving of carbides. The principal objective is to put hardening phases into solution and dissolve some carbides. After aging, the resulting microstructure of these wrought alloys consists of large grains that contain the principal aging phases (γ', γ'', η) and a heavy concentration of carbides in the grain boundaries. The lower solution-treating temperature dissolves the principal aging phases without grain growth or significant carbide solution.

For some wrought superalloys (such as Nimonic 80A and Nimonic 90), an intermediate solution-treating temperature is selected to produce a compromise of the properties. For other alloys (such as Udimet 500 and Udimet 700), the intermediate-temperature aging treatment is used to tailor the grain boundaries for improved creep-rupture properties.

Quenching. The purpose of quenching after solution treating is to maintain, at room temperature, the supersaturated solid solution obtained during solution treating. Quenching permits a finer age-hardening precipitate size. Cooling methods commonly used include oil and water quenching as well as various forms of air or inert gas cooling. Internal stresses resulting from quenching can also accelerate overaging in some age-hardenable alloys.

Aging treatments strengthen age-hardenable alloys by causing the precipitation of additional quantities of one or more phases from the supersaturated matrix that is developed by solution treating. Factors that influence the selection and number of aging steps and aging temperature include:

- Type and number of precipitating phases available
- Anticipated service temperature
- Precipitate size
- The combination of strength and ductility desired and heat treatment of similar alloys

Typical heat treatments of wrought age-hardenable superalloys are given in Table 3. Because dimensional changes can occur during aging, it is recommended that finish machining be done after aging.

Table 3 Typical solution-treating and aging cycles for wrought superalloys

Note: Alternate treatments may be used to improve specific properties.

(a) If furnace size/load prohibits fast heat up to initial age temperature, a controlled ramp up from 590 to 730 °C (1100 to 1350 °F) is recommended.

(b) To provide adequate quenching after solution treating, it is necessary to cool below about 540 °C (1000 °F) rapidly enough to prevent precipitation in the intermediate temperature range. For sheet metal parts of most alloys, rapid air cooling will suffice. Oil or water quenching is frequently required for heavier sections that are not subject to cracking.

(c) Heat treatment of lnconel 706 to enhance tensile properties instead of creep resistance for tensile-limited applications

Aging Precipitates. Principal aging phases in the superalloys usually include one or more of the following: γ' (Ni_3Al or Ni_3Al,Ti), η (Ni_3Ti), or γ" (body-centered tetragonal Ni_3Nb). Secondary phases that may be present include: carbides ($M_{23}C_6$, M_7C_3, M_6C, and MC), nitrides (MN), carbonitrides (MCN), and borides (M_3B_2), as well as Laves phase (M_2Ti) and δ phase (orthorhombic Ni_3Nb). The above phases occur principally in nickel-base alloys. The primary phases in cobalt-base alloys are $M_{23}C_6$, M_7C_3, M_6C, and MC. The primary phases in iron-base superalloys will be similar to those in nickel alloys, although η is more apt to be found because the Ti-to-Al ratio is generally higher in iron alloys than in nickel alloys.

When more than one phase is capable of precipitating from the alloy matrix, judicious selection of a single aging temperature (or a double aging treatment that produces different sizes and types of precipitates at different temperatures) is important. The principal strengthening precipitates are γ' or γ", while other precipitates such as η, δ, or Laves phase can provide grain size control in nickel-iron superalloys (see, for example, the next section "Thermomechanical Processing"). In some alloys, if composition has not been carefully controlled, undesirable phases, such as σ and μcan also form either during heat treatment or, more commonly, during service. These precipitates, known as TCP (topologically close-packed) phases, are composed of close-packed layers of atoms parallel to {111} planes of the γmatrix. Usually harmful, they may appear as long plates or needles, often nucleating on grain-boundary carbides. The formulae for σ and μ are given in Table 4. Alloys containing a high level of body-centered cubic (bcc) transition metals (tantalum, niobium, chromium, tungsten, and molybdenum) are most susceptible to TCP phase formation.

Table 4 Constituents observed in superalloys

Phase	**Crystal structure**	**Lattice parameter, nm**	**Formula**	Comments
γ'	fcc (ordered *L*1$_2$)	0.3561 for pure Ni_3Al to 0.3568 for $Ni_3(Al_{0.5}Ti_{0.5})$	Ni_3Al $Ni_3(Al, Ti)$	**Principal strengthening phase in many nickel- and nickel-iron-base superalloys; crystal lattice varies slightly in size (0 to 0.5%) from that of austenite matrix; shape varies from spherical to cubic; size varies with exposure time and temperature. Gamma prime is spherical in iron-nickel-base and in some of the older nickel-base alloys, such as Nimonic 80A and Waspaloy. In the more recently developed nickel-base alloys, γ' is generally cuboidal. Experiments have shown that variations in molybdenum content and in the aluminum/titanium ratio can change the morphology of γ. With increasing γ/γ' mismatch, the shape changes in the following order: spherical, globular, blocky, cuboidal. When the γ/γ' lattice mismatch is high, extended exposure above 700 °C (1290 °F) causes undesirable η(Ni_3Ti) or δ(Ni_3Nb) phases to form.**
η	hcp (*D*0$_{24}$)	a_o = 0.5093 c_o = 0.8276	Ni_3Ti (no solubility for other elements)	**Found in iron-, cobalt-, and nickel-base superalloys with high titanium/aluminum ratios after extended exposure; may form intergranularly in a cellular form or intragranularly as acicular platelets in a Widmanstätte pattern**
γ"	bct (ordered *D*0$_{22}$)	a_o = 0.3624 c_o = 0.7406	Ni_3Nb	**Principal strengthening phase in Inconel 718; γ'' precipitates are coherent disk-shaped particles that form on the {100} planes (avg diam approximately 600 Å, thickness approximately 50 to 90 Å); Bright-field TEM examination is unsatisfactory for resolving γ'' due to the high density of the precipitates and the strong contrast from the coherency strain field around the precipitates. However, dark-field TEM examination provides excellent imaging of the γ'' by selective imaging of precipitates that produce specific superlattice reflections. In addition, γ'' can be separated from γ' using the dark-field mode, because the γ'' dark-field image is substantially brighter than that of γ'.**
Ni_3Nb (δ)	Orthorhombic (ordered Cu_3Ti)	a_o = 0.5106-0.511 b_o = 0.421-0.4251 c_o = 0.452-0.4556	Ni_3Nb	**Observed in overaged Inconel 718; has an acicular shape when formed between 815 and 980 °C (1500 and 1800 °F); forms by cellular reaction at low aging temperatures and by intragranular precipitation at high aging temperatures**

MC	Cubic	a_o = 0.430-0.470	TiC NbC HfC	**Titanium carbide has some solubility for nitrogen, zirconium, and molybdenum; composition is variable; appears as globular, irregularly shaped particles that are gray to lavender; "M" elements can be titanium, tantalum, niobium, hafnium, thorium, or zirconium.**
$M_{23}C_6$	fcc	a_o = 1.050-1.070 (varies with composition)	$Cr_{23}C_6$ $(Cr,Fe,W,Mo)_{23}C_6$	**Form of precipitation is important; it can precipitate as films, globules, platelets, lamellae, and cells; usually forms at grain boundaries; "M" element is usually chromium, but nickel-cobalt, iron, molybdenum, and tungsten can substitute.**
M_6C	fcc	a_o = 1.085-1.175	Fe_3Mo_3C Fe_3W_3C-Fe_4W_2C Fe_3Nb_3C Nb_3Co_3C Ta_3Co_3C	**Randomly distributed carbide; may appear pinkish; "M" elements are generally molybdenum or tungsten; there is some solubility for chromium, nickel-niobium, tantalum, and cobalt.**
M_7C_3	Hexagonal	a_o = 1.398 c_o = 0.4523	Cr_7C_3	**Generally observed as a blocky intergranular shape; observed only in alloys such as Nimonic 80A after exposure above 1000 °C (1830 °F), and in some cobalt-base alloys**
M_3B_2	Tetragonal	a_o = 0.560-0.620 c_o = 0.300-0.330	Ta_3B_2 V_3B_2 Nb_3B_2 $(Mo,Ti,Cr,Ni,Fe)_3B_2$ Mo_2FeB_2	**Observed in iron-nickel- and nickel-base alloys with about 0.03% B or greater; borides appear similar to carbides, but are not attacked by preferential carbide etchants; "M" elements can be molybdenum, tantalum, niobium, nickel, iron, or vanadium.**
MN	Cubic	a_o = 0.4240	TiN (Ti,Nb,Zr)N (Ti,Nb,Zr)(C,N) ZrN NbN	**Nitrides are observed in alloys containing titanium, niobium, or zirconium; they are insoluble at temperatures below the melting point; easily recognized as-polished, having square to rectangular shapes and ranging from yellow to orange**
μ	Rhombohedral	a_o = 0.475 c_o = 2.577	Co_2W_6 $(Fe,Co)_7(Mo,W)_6$	**Generally observed in alloys with high levels of molybdenum or tungsten; appears as coarse, irregular Widmanstätten platelets; forms at high temperatures**
Laves	Hexagonal	a_o = 0.475-0.495 c_o = 0.770-0.815	Fe_2Nb Fe_2Ti Fe_2Mo Co_2Ta Co_2Ti	**Most common in iron-base and cobalt-base superalloys; usually appears as irregularly shaped globules, often elongated, or as platelets after extended high-temperature exposure**
σ	**Tetragonal**	**a_o = 0.880-0.910 c_o = 0.450-0.480**	**FeCr FeCrMo CrFeMoNi CrCo CrNiMo**	**Most often observed in iron- and cobalt-base superalloys, less commonly in nickel-base alloys; appears as irregularly shaped globules, often elongated; forms after extended exposure between 540 and 980 °C (1005 to 1795 °F)**

The size distribution of precipitates is affected by aging temperature. Exposure to temperatures higher than the optimum aging temperature results in a decrease in strength through the process of overaging (coarsening of precipitates); at still higher temperatures, resolution may occur. High aging temperatures will produce coarser γ' particles than lower

temperatures and result in higher creep-rupture properties. For optimum short-time elevated-temperature properties, small, finely dispersed particles of γ' precipitate are desired. Therefore, final aging temperatures are lower than those used to obtain high creep-rupture properties. For all γ' dispersions, care must be taken to ensure the correct carbide distribution.

Double-Aging Treatment. A two-step aging treatment is commonly used to control the size distribution of γ' and γ'' precipitates. A principal reason for two-step aging sequences, in addition to γ' or γ'' control, is to precipitate or control grain boundary carbide morphology. In some alloys, such as Incoloy 901 and A-286, MC films may form along grain boundaries and reduce ductility.

Double or multistep aging treatments vary according to the alloy type and design objectives. In some alloys, a second aging step up to about 850 °C (1560 °F) is added (see Examples 1 and 2 below).

In other alloys, however, aging may involve an initial treatment in the range of 850 to 1100 °C (1560 to 2010 °F) over a period of up to 24 h. Aging at one or more lower temperatures, for example at 760 °C (1400 °F) for 16 h, completes the precipitation of γ'. The finer γ' produced in the second aging treatment is advantageous for tensile strength as well as for rupture life. This type of aging treatment is used for nickel-base superalloys such as Udimet 700, Astroloy, and Udimet 710.

Example 1: Double-Aging Treatment of A-286.

Adding a second aging treatment can improve properties to meet a requirement. For example, borderline values of yield strength, 615 and 630 MPa (89 and 91 ksi), were obtained in two heats of material with a heat treatment of:

- 900 °C (1650 °F) solution treatment for 2 h and oil quench
- Aging treatment of 705 °C (1300 °F) for 16 h with air cooling

By aging a second time at 650 °C (1200 °F) for 16 h (air cooled), the yield strengths were improved to 635 and 698 MPa (92 and 101 ksi).

Example 2: Double-Aging Sequence of Udimet 500 for Stabilization of Grain Boundary Carbides.

Udimet 500 is typical of wrought precipitation-hardened superalloys that contain MC and $M_{23}C_6$ carbides and are strengthened by γ'. For a good balance of tensile strength and stress-rupture life, the alloy is:

- Solution heat treated at 1080 °C (1975 °F) for 4 h (air cooled)
- Stabilized at 845 °C (1550 °F) for 24 h (air cooled)
- Aged at 760 °C (1400 °F) for 16 h (air cooled)

The solution exposure dissolves all phases except MC carbides, and γ' precipitates nucleate during cooling from the solution temperature. The stabilization at 845 °C (1550 °F) precipitates discontinuous $M_{23}C_6$ at grain boundaries as well as γ'. Final aging increases the volume fraction of γ'. The grain boundary $M_{23}C_6$ increases stress-rupture life as long as it is not a continuous carbide film, which markedly decreases rupture ductility.

Thermomechanical Processing. In recent years there has been more interest in the interdependence of hot working and heat-treating operations. In many critical applications the desired final properties are not attainable via heat treatment if the hot working operation has not been conducted under controlled temperature and deformation parameters. This requires a study of hot working and heat treating, known as thermomechanical processing. One application of thermomechanical processing is the development of direct age 718 for turbine disk applications (Ref 1). Proper heating temperatures and forging operations also influence the microstructure and distribution of phases in alloys such as 718.

Grain Size Control. An important objective of thermomechanical processing is grain size control (Ref 2, 3, 4). For example, grain structure may be controlled by thermomechanical processing in several iron-nickel-base alloys that have two precipitates present, such as the primary strengthening precipitate (γ'' Ni_3Nb in Inconel 718 and γ' Ni_3Ti in Inconel

901) and a secondary precipitate (δ in Inconel 718 and ηNi_3Ti in Inconel 901) (Ref 3, 4). The secondary precipitate is produced first, by an appropriate heat treatment (8 h at 900 °C, or 1650 °F, for 901), followed by working at about 950 °C (1740 °F), below the η solvus. Final working is carried out below the recrystallization temperature, and the alloy is subsequently recrystallized below the η solvus. Finally, the alloy is aged by standard procedures. The result is a fine-grain alloy with higher tensile strength and improved fatigue resistance.

Other thermomechanical working schedules are used to produce a double necklace structure of fine grains surrounding the large grains formed during high-temperature recrystallization. Reductions of 25 to 50% are needed in the final working operations at 1080 to 1110 °C (1975 to 2030 °F) to produce the small recrystallized grains in cast/wrought René 95.

General Guidelines and Potential Problems

Surface-Related Problems. Although superalloys offer resistance to surface degradation during elevated-temperature service, heat treatment temperatures (particularly solution treatment) can degrade surface characteristics. The potential forms of surface degradation include oxidation, carbon pickup, alloy depletion, and contamination.

Oxidation. In general, superalloys have good oxidation resistance within their normal range of service temperature and above their aging temperatures (typical range 760 to 980 °C, or 1400 to 1800 °F) depending on the alloy. Others may require coatings to provide suitable resistance in the service environment, such as blade and vane alloys for turbine engines and compressors. However, at higher temperatures, such as those used for solution treating, these alloys are susceptible to intergranular oxidation, a defect that adversely affects thermal fatigue.

Oxidation resistance is enhanced by adding chromium, aluminum, and certain other elements. Chromium allows formation of a protective chromium oxide and is most beneficial at intermediate temperatures and below ($\lesssim$870 °C, or 1600 °F), or in the presence of adequate aluminum permits the formation of aluminum oxide, which is more protective at higher temperatures (>870 °C, or 1600 °F). The principal mode of intergranular attack involves preferential oxidation of chromium, aluminum, titanium, zirconium, and boron. Molybdenum increases susceptibility to intergranular attack in age-hardenable alloys. In relation to intergranular oxidation, aluminum is preferable to titanium as a hardening element because:

- Increased aluminum reduces formation of the η phase from γ'
- Aluminum oxide provides a denser and less permeable barrier to the diffusion of oxygen
- Lower density

However, a smooth tight oxide layer is not possible in chromium-free low-expansion (Invar-type) superalloys such as Incoloy alloys 903, 907, and 909 and Pyromet alloys CTX-1, CTX-3, and CTX-909.

Carbon pickup can occur if the solution-treating atmosphere has a carburizing potential. For instance, the carbon content of the surface of A-286 has been observed to increase from 0.05 to 0.30%. The added carbon forms a stable carbide (TiC), thus removing titanium from solid solution and preventing normal precipitation hardening in the surface layers. TiN can be formed in the same manner as a result of nitrogen contamination.

Alloy Depletion. In addition to oxidation, exposure to high-temperature environments can cause changes in the composition of the alloy near the surface. As certain elements are preferentially consumed by the scale layer, the bulk composition can become depleted. In addition, some alloys can be very susceptible to deboronization. This can affect the properties of the surface layers and can be of considerable concern, for instance in sheet products.

Miscellaneous Contaminants. All exposed surfaces of superalloy parts should be kept free of dirt, fingerprints, oil, grease, forming compounds, lubricants, and scale. Lubricants or fuel oils that contain sulfur compounds are particularly active in corroding and embrittling the metal surface by first forming Cr_2S_3 and then, as the attack progresses, also forming a $Ni\text{-}Ni_3S_2$ eutectic that melts at 645 °C (1190 °F), particularly at low pressures of less than 10^{-2} Pa (10^{-4} torr) in vacuum.

Scale and slag from furnace hearths are another source of contamination. Contact with steel scale, slag, and furnace spallings should be avoided; low-melting constituents can form on the metal surface and promote corrosion.

Protective atmospheres are used in annealing or solution treating if heavy oxidation cannot be tolerated. If oxidation can be tolerated, because of subsequent stock removal, superalloys can be solution-treated in air or in the normal mixture of air and combustion products found in gas-fired furnaces. A vacuum environment is desirable.

Vacuum atmosphere, generally below $\frac{1}{4}$ Pa (2×10^{-3} torr), is commonly used above 815 °C (1500 °F). It is particularly desirable when parts are at or close to final dimensions.

Inert Gas. Dry argon, with a dew point of -50 °C (-60 °F) or lower, should be used if no oxidation can be tolerated. It is mandatory that this type of atmosphere be used in a sealed retort or sealed furnace chamber. A purge of at least ten times the volume of the retort is recommended before the retort is placed in the furnace. The argon must be kept flowing continually during and after the treatment until the workpieces have cooled nearly to room temperature, to prevent the formation of an oxide film.

Alloys containing stable-oxide formers such as aluminum and titanium, with or without boron, must be bright annealed in a vacuum or in a chemically inert gas such as argon. If used, argon must be pure and dry with a dew point of -50 °C (-60 °F) or lower. If the argon has a slightly higher dew point, but not more than -40 °C (-40 °F), oxidation will be limited to a thin surface film that can usually be tolerated.

Hydrogen. Dry hydrogen, with a dew point of -50 °C (-60 °F) or lower, is used in preference to dissociated ammonia for bright annealing. If the hydrogen is prepared by catalytic gas reactions instead of by electrolysis, residual hydrocarbons, such as methane, should be limited to about 50 ppm, to prevent carburizing. Hydrogen is not recommended for bright annealing of alloys containing significant amounts of elements (such as aluminum or titanium) that form stable oxides not reducible at normal heat-treating temperatures and dew points. Hydrogen is not recommended for annealing or solution treating alloys that contain boron, because of the danger of deboronization through formation of boron hydrides. Titanium hydrides can also form.

Exothermic Atmosphere. A lean and dilute exothermic atmosphere is relatively safe and economical. The surface scale formed in such an atmosphere can be removed by pickling or by salt bath descaling and pickling. Such an atmosphere, formed by burning fuel gas with air, contains about 85% nitrogen, 10% carbon dioxide, 1.5% carbon monoxide, 1.5% hydrogen, and 2% water vapor. This atmosphere will produce a scale rich in chromium oxides.

Endothermic atmospheres prepared by reacting fuel gas with air in the presence of a catalyst are not recommended, because of their carburizing potential. Similarly, the endothermic mixture of nitrogen and hydrogen formed by dissociating ammonia is not used, because of the probability of nitriding.

Atmosphere for Aging. Air is the most common aging atmosphere. The smooth, tight oxide layer that is formed is usually unobjectionable on the finished product (except when heat treating chromium-free low-expansion superalloys). However, if this oxide layer must be minimized, a lean exothermic gas (air-to-gas ratio, about 10 to 1) or vacuum can be employed. It will not entirely prevent oxidation, but the oxide layer will be very light. The use of gases containing hydrogen and carbon monoxide for aging cycles is dangerous because of the explosion hazard at temperatures below 760 °C (1400 °F).

Furnace Equipment. Basic equipment considerations seldom differ from those influencing the selection of furnaces for heat treating steel. In general, the temperature-control limits are ±14 °C (±25 °F) and temperature may range up to about 1315 °C (2400 °F). Belt conveyor furnaces, although widely used for production annealing, are less gastight than roller-hearth furnaces of the same volume. Batch heating for annealing or solution treating is usually done in box furnaces. These may have provisions for purging, preheating, and quenching, if the high-temperature compartment is supplemented by other chambers.

Aging of precipitation-hardenable superalloys, commonly in the range of 650 to 900 °C (1200 to 1650 °F), is usually done in box furnaces, with or without protective atmospheres. The usual operating-temperature tolerance is ±14 °C (±25 °F). Continuous furnaces are seldom used, because of the long aging cycles. Salt baths are not recommended, because reaction could occur between chloride in the bath and the alloy surface during the long-time immersion required for aging. Salt baths can be used satisfactorily for solution treating, however.

Vacuum furnaces are used for heat treating some alloys. Heating may be accomplished by resistance elements or by induction. Furnace design dictates a batch operation. Cooling can be accomplished in a vacuum retort pressurized with an inert gas that provides conductive cooling after heating is discontinued. Further details are provided in the article "Heat Treating in Vacuum Furnaces and Auxiliary Equipment" in this Volume.

Fixtures for holding finished parts or assemblies during heat treatment may be either the support type or the restraint type. For alloys that must be cooled rapidly from the solution-treating temperature, the best practice is to employ minimum fixtures during solution treating and quenching and to control dimensional relations by using restraining fixtures during aging.

Support fixtures are used when restraint is not required or when the part itself provides sufficient self-restraint. A support fixture also aids in handling parts and helps the part to support its own weight. Long narrow pieces, such as tubes or bolts, are most easily fixtured by hanging vertically. Parts that have a large flat surface, such as rings, cylinders, and beams, can be placed on a flat furnace tray or plate. For slightly asymmetrical parts, special supports can be built up from a flat tray. If these supports are fabricated by welding, they must be stress relieved prior to use.

Asymmetrical parts can be supported in several ways. One method is to lay the part on a tray of sand, making certain that most of the bottom area is well supported. Alluvial garnet sand is most commonly used as the supporting medium. Another method of support is a ceramic casting formed to the shape of the part. However, this method is costly and subject to size limitations. Turbine blades and asymmetrical ducting are examples of parts that can be supported either in a sand tray or by ceramic castings.

Restraint fixtures are generally more complicated than support fixtures and may require machined grooves, lugs, or clamps to hold parts to a given shape. For example, to maintain symmetry and roundness in an alloy A-286 frame assembly during aging, the assembly was processed on a flat plate into which grooves had been machined. These grooves accepted the rims on the outer and inner shrouds and held them in restraint during heat treatment. To prevent the center hub from rising or dropping in relation to the outer shroud, both the hub and the shroud were clamped to the grooved-plate fixture.

Some straightening of parts is possible in aging fixtures of the type described above. A slightly distorted part can be forced into the fixture and clamped. Some stress relieving will occur along with aging. However, fixtures for hot sizing are not always successful, because of the high creep strength of these alloys at the aging temperature.

Threaded fasteners are not recommended for clamping because they are difficult to remove after heat treatment. A slotted bar held in place by wedges is preferable.

Usually, the coefficient of expansion of both the fixture and part should be nearly the same. However, in some applications, the fixture is purposely made from a material having different expansion characteristics, in order to apply pressure to the part as the temperature increases.

Wrought Superalloy Heat Treatment

The heat treatment of wrought superalloys can be subdivided according to the following alloy categories:

- Precipitation-strengthened nickel-iron-base superalloys
- Precipitation-strengthened nickel-base superalloys
- Solution-strengthened iron-, nickel-, and cobalt-base superalloys

Solid-solution-strengthened iron-, nickel-, and cobalt-base superalloys are generally distinguishable from the precipitation-strengthened superalloys by their relatively low content of precipitate-forming elements such as aluminum, titanium, or niobium. There are, of course, some exceptions to this, particularly as regards niobium content. Typical compositions for precipitation-strengthened and solid-solution-strengthened superalloys are given in Table 1.

Precipitation-Strengthened Nickel-Iron-Base Superalloys

There is also an important distinction between the nickel-base and nickel-iron precipitation-strengthened superalloys. Many of the nickel-iron alloys allow precipitation of additional intermetallics (such as η, δ, and Laves phases) in addition to the principal strengthening precipitates (γ' and/or γ"). These additional precipitates, with appropriate heat treatment, can provide some grain size control in nickel-iron superalloys. For example:

- The η phase in Inconel 901 and A-286 reduces grain growth when temperatures are below the η solvus
- The δ phase can control grain size in γ"-strengthened superalloys such as Inconel 718
- The Laves phase (solvus at about 1040 °C, or 1900 °F) in Incoloy 909 and Pyromet CTX3M controls grain size when annealing in a temperature range of 980 to 1010 °C (1800 to 1850 °F)

A specific example of grain size control with the η phase is described below.

Example 3: Control of Grain Growth in A-286 with η.

In A-286, the γ' solvus is approximately 855 °C (1575 °F) and the η solvus is approximately 910 °C (1675 °F). The alloy can be worked and heat treated above the η solvus, or the γ' can be fully dissolved with some η phase retained for grain size control. A-286 has been processed to fine grain sizes by finish forging at temperatures in the vicinity of the η solvus, solution treating below the η solvus but above the γ' solvus (for example, hold at 900 °C, or 1650 °F) for 2 h and oil quench), then aging below the γ' solvus (for example, 720 °C, or 1325 °F, for 16 h and air cool). Recrystallization occurs above the γ' solvus either during forging or solution heat treatment, but the η phase controls grain growth. If the alloy is solution heat treated above the η solvus (for example, at 980 °C, or 1800 °F, for 1 h with oil quenching), a coarser grain size results. Table 5 shows typical tensile and stress-rupture data for A-286 obtained by each approach. The finer-grain-size material has better room-temperature tensile strength, better stress rupture ductility (including notched bar rupture ductility), but lower stress-rupture life.

Table 5 Effect of heat treatment on the properties of A-286

Heat treatment	**Tensile properties at 21 °C (70 °F)**	Stress rupture at 650 °C (1200 °F)

	0.2% Yield strength		Ultimate tensile strength		Elongation %	Reduction in area, %	with 450 MPa (65 ksi)		
	MPa	ksi	MPa	ksi			Life, h	Elongation, %	Reduction in area, %
980 °C (1800 °F) for 1 h, oil quench (OQ) + 720 °C (1325 °F) for 16 h, air cool	690	100	1070	156	24	46	85	10	**15**

Alloy Types. Precipitation-strengthened nickel-iron-base superalloys can be grouped into two classes according to the main strengthening phase. One class consists of alloys strengthened by the γ' phase. This class includes alloys such as A-286, which contain relatively low levels of nickel (25 to 35 wt%), and alloys such as Incoloy 901 and Inconel X-750, which contain higher levels of nickel (more than 40 wt%) and also contain higher volume fractions of γ' for increased strength. Iron-rich Incoloy 903 and 909, which are iron-nickel-cobalt alloys developed to exhibit low coefficient of thermal expansion properties along with high strength, are also strengthened by γ' precipitates.

The second class of nickel-iron-base superalloys includes alloys strengthened primarily by the γ" phase. These alloys are nickel-rich and contain niobium for formation of γ", and are represented by Inconel alloys 706 and 718. Inconel 718 is particularly important. In 1989, 45% of all wrought nickel-base and nickel-iron-base superalloys produced was Inconel 718.

Effects of Cold Working on Heat Treatment Response. Cold working of age-hardenable nickel-iron-base superalloys affects the response of the alloy during heat treatment. Cold work affects the recrystallization and grain growth behavior during subsequent solution treatment, and also the reaction kinetics of aging. The cold working itself is usually performed on solution-treated alloys because of the markedly lower strength and increased ductility of the material before aging (see Table 6).

Table 6 Typical effects of aging on room-temperature mechanical properties of solution-treated heat-resisting alloys

Alloy	Yield strength (0.2% offset				Elongation in 50 mm (2 in.), %	
	Not aged		Aged			
	MPa	ksi	MPa	ksi	Not aged	Aged
A-286	240	35	760	110	52	**33**
René 41	620	90	1100	160	45	**15**
X-750	410	60	650	92	45	**24**

Haynes alloy 25	**480**	**69**	**480**	**70**	**55**	**45**

Effect of Cold Work on Grain Growth during Solution Treatment. Larger amounts of cold work refine the grain size during solution treatment, but smaller amounts of cold work can lead to critical grain growth. The effect of varying amounts of cold work on grain growth in A-286 during solution treating is illustrated in Fig. 1. The initial material was solution treated with a maximum grain size of ASTM 5. Cold working in the range of 1 to 5% caused excessive grain growth during subsequent solution treating at 900 °C (1650 °F). Above about 5% of cold work, critical grain growth did not occur, and the recrystallized grain size decreased with increasing cold work. Excessive grain growth, especially excessive localized grain growth, would likely degrade tensile properties. Therefore, on parts subjected to cold or hot work prior to solution treating, the critical amount of work (about 1 to 6% cold work, depending on the alloy, and about 10% hot work) must be exceeded in all areas to avoid the growth of abnormally large grains. This rule applies to items such as cold-headed bolts, spun or stretch-formed sheets, and parts formed by simple bending.

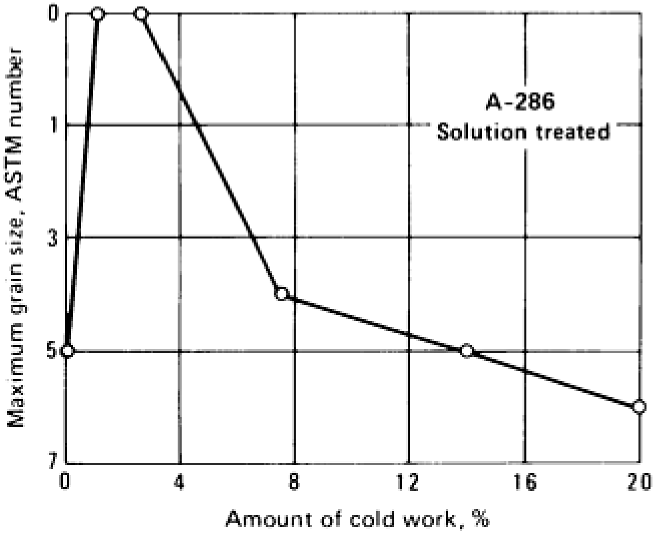

Fig. 1 Effect of cold work on grain size of A-286 alloy solution treated at 900 °C (1650 °F) for 1 h and oil quenched

Effect of Cold Work on Aging Response. Cold working accelerates the aging reaction, causing the early appearance of precipitates at normal aging temperature and the appearance of a precipitate at temperatures below the normal aging temperature if the alloy is cold worked sufficiently and held at temperature long enough. In other words, cold working can make a material more prone to overaging at the normal aging temperature. Even relatively small amounts of residual strain can lead to strain-induced overaging of the low-expansion (Invar-type) superalloys such as Incoloy 907, 909, and Pyromet CTX-3 and CTX-909. This effect can result in an extreme loss in tensile properties. Thus, care must be taken to provide strain (dislocation)-free structures prior to aging. Properly charted information correlating cold work with aging response, however, can be used to shorten the required aging period or to lower the normal aging temperature. The effect of cold work and aging on hardness in A-286 is shown in Fig. 2.

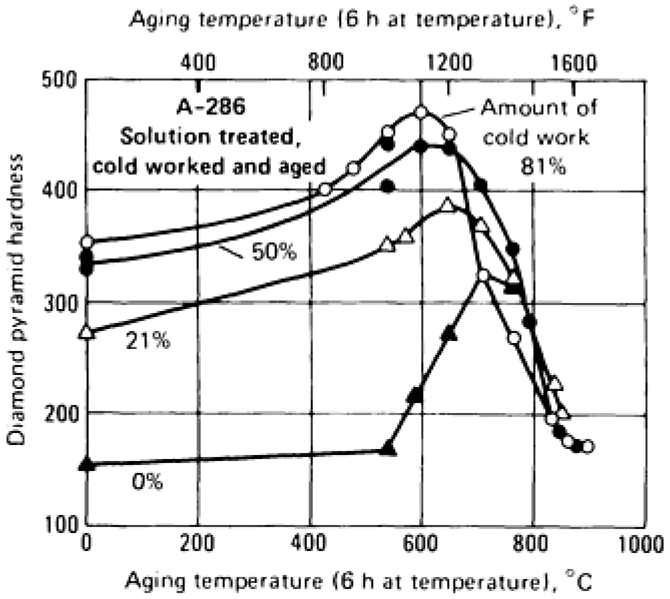

Fig. 2 Effect of cold work and aging on diamond pyramid hardness of A-286

The hardness after cold working and before aging, as well as the peak hardness after aging, increases greatly with increasing amounts of cold rolling. The temperature at which peak hardness is attained decreases with increasing amounts of reduction. The temperature at which softening occurs also decreases with increasing amounts of deformation. In Fig. 2, for example, the material cold worked 81% and then aged at 760 °C (1400 °F) for 16 h is softer than material that was not cold worked before being aged.

Double Aging of Cold Worked Parts to Obtain Uniformity of Properties. In parts that have been cold worked nonuniformly, higher-than-normal aging temperatures are sometimes used, followed by a second aging cycle at lower-than-normal aging temperature. For example, in A-286 parts with varying amounts of cold work, double aging at 760 °C (1400 °F) and 720 °C (1300 °F), respectively, provides more uniform hardness, short-time tensile properties, and creep-rupture properties than the normal 720 °C (1325 °F) aging treatment. The higher aging temperature also improves the structural stability of the part in service.

Heat Treatment of Nickel-Iron-Base Alloys Strengthened by γ'. For the nickel-iron-base superalloys strengthened by γ', heat treatments are designed to control grain size and develop the desired morphology of possible phases, primarily γ', η, and MC carbides. Precipitation of the η phase occurs at temperatures higher than the γ' solvus, and can provide control of grain growth during thermomechanical processing or during heat treatment (see, for instance, Example 3 in this article). Adding a second aging treatment can also improve properties (see Example 1).

Acceptable mechanical properties do not always result from the solution treating and aging procedure first tried for a given alloy or application. To develop specified properties, changes of the following kinds are often required:

- Adjust the solution temperature or time
- Adjust the aging temperature
- Add an intermediate (stabilizing) aging treatment at a temperature higher than that of the final aging
- Add a second (final) aging treatment at a lower temperature
- Adjust one or both aging temperatures in a double aging cycle
- Add a third aging treatment
- Increase aging time

An example for A-286 is shown in Table 7, which shows the effects of alternative approaches to the problem of insufficient notch ductility in heat treated A-286 alloy (namely, an additional aging treatment and the substitution of a higher aging temperature for single aging). Although both approaches provided required creep-rupture properties, the

higher aging temperature (with no increase in the solution-treating temperature) is recommended over the additional aging treatment.

Table 7 Effects of alternative aging treatments on rupture properties of A-286

Treatment	Creep rupture[a]		
	Life, h	**Elongation in 50 mm (2 in.), %**	Location of failure
Original heat treatment[b]			
900 °C (1650 °F), 2 h, oil quench; 720 °C (1325 °F), 16 h, air cool	7-69	. . .	**Notch**
Revised heat treatments[c]			
Original plus additional age at 650 °C (1200 °F), 12 h, air cool	74-142	5.6-7.7	**Smooth bar**

(a) Specification requirements for creep-rupture at 650 °C 1200 °F) and 450 MPa (65 ksi); life, 23 h min; no failure in notch permitted.

(b) Ten specimens tested.

(c) Five specimens for each treatment

Such procedures can be especially important when high-temperature annealing (such as during brazing) results in a coarse-grain microstructure. This is definitely the case for low-expansion superalloys, because initial aging temperature and time must be increased to provide overaging necessary for improved notched bar rupture strength if grain size is coarse.

Heat Treatment of Incoloy 901. Incoloy 901 has a γ' solvus of approximately 940 °C (1725 °F) and an η solvus of approximately 995 °C (1825 °F). Just as for A-286 (Example 3), solution heat treating above the γ' solvus but below the η solvus is used to obtain a finer grain structure (for improved tensile properties), and solution heat treating above the η solvus is used to yield a coarser grain structure (for improved creep characteristics). In addition, for Incoloy 901, a stabilization heat treatment is carried out before aging to achieve a desirable grain-boundary carbide morphology. The stabilization heat treatment promotes formation of globular MC (primarily TiC) carbides as opposed to a continuous grain boundary film. Low stress-rupture ductility is associated with a continuous intergranular MC film, while the globular MC morphology promotes good rupture life and ductility.

Heat treatment to achieve a coarser grain size of ASTM 2 to 4, with discrete intergranular carbides and a γ' strengthened matrix might be:

- Solution heat treating at 1080 to 1105 °C (1975 to 2025 °F) for 2 h (air cooling or faster)
- Stabilizing at 775 to 800 °C (1425 to 1475 °F) for 2 to 4 h (air cooling)
- Aging at 705 to 745 °C (1300 to 1375 °F) for 24 h (air cooling)

To preserve a finer grain size achieved by forging, lower solution, stabilizing, and aging temperatures are chosen. Heat treatment for finer grain size would be:

- Solution heat treating at 980 to 1040 °C (1800 to 1900 °F) for 1 to 2 h (air cooling or faster)
- Stabilizing at 705 to 730 °C (1300 to 1350 °F) for 6 to 20 h (air cooling or faster)
- Aging at 635 to 665 °C (1175 to 1225 °F) for 12 to 20 h (air cooling)

This approach typically yields a dynamically recrystallized grain size of ASTM 5 to 7, with grain boundaries strengthened by discrete carbides and possibly containing some η phase, and a matrix strengthened by γ' precipitates. Tensile properties for an Incoloy 901 forged and heat-treated turbine disk that are representative of the above two heat treatment approaches are presented for room temperature and 540 °C (1000 °F) in Tables 8 and 9, respectively. The lower solution temperature yields higher tensile strengths and ductility.

Table 8 Tensile properties at various locations in disk forgings of Incoloy 901 in two heat-treated conditions

Source: Ref 6

It is important to note, however, that not only heat treatment influences tensile properties; the control of structure during thermomechanical processing is also important. A method for achieving fine grain structures in Incoloy 901 (less than ASTM 10) by controlling structure during thermomechanical processing with η phase (Ref 2) is briefly described in the section "Thermomechanical Processing" in this article. Figure 3 shows the effect of solution temperatures from 955 °C (1750 °F) to 1095 °C (2000 °F) and grain sizes from ASTM 2 to 12 on tensile properties of Incoloy 901 processed using this method. The high-cycle fatigue strength of Incoloy 901 doubled as a result of the reduction in grain size from ASTM 2 to 12 (Table 10). The low-cycle fatigue also improved greatly with decreasing grain size (Table 11).

Table 10 Effect of grain size on the high-cycle fatigue properties of Incoloy 901 at 455 °C (850 °F)

An example of the effect of the stabilization heat treatment for Incoloy 901 is given in Table 12. Adding the stabilization treatment greatly improved the rupture ductility, although at some sacrifice of yield strength and rupture life.

Table 12 Effect of stabilization on typical properties of Incoloy 901

(a) Heat treatment: 1120 °C (2050 °F) for 2 h, water quench; 745 °C (1375 °F) for 24 h, air cool.

(b) Heat treatment: 1120 °C (2050 °F) for 24 h, water quench; 815 °C (1500 °F), 4 h; air cool; 745 °C (1375 °F), 24 h; air cool

Adding a second aging treatment can improve selected properties as needed. In one application, single aging at 720 °C (1325 °F) for 24 h (air cooled), after a 2-h 1085 °C (1985 °F) solution and stabilization (water quenched) failed to provide sufficient yield strength to meet specifications for room-temperature tensile strength. A second aging treatment at 650 °C (1200 °F) for 12 h (air cooled) provided additional strength to meet requirements. Table 13 lists the properties obtained by the two treatments.

Table 13 Effect of single and double aging on room-temperature properties of Incoloy 901

	Ultimate tensile strength		**Yield strength**		**Elongation in 50 mm (2 in.), %**	Reduction in area, %
	MPa	**ksi**	**MPa**	**ksi**		
Specification	1140	165	827	120	12	**15**

(a) Solution treated at 1085 °C (1985 °F) for 2 h, water quenched; aged at 770 °C (1450 °F) for 2 h, air cooled; aged at 720 °C (1325 °F) for 24 h, air cooled.

(b) Re-aged at 650 °C (1200 °F} for 12 h and air cooled

In another Incoloy 901 application, a problem of low room-temperature yield strength and low rupture ductility was solved by increasing the temperature of the 2-h stabilization (and air cooling) treatment from 775 °C (1425 °F) to 790 °C (1450 °F), and by adding a second aging treatment. Table 14 lists the mechanical properties obtained using the original and the revised heat treatments.

Table 14 Effects of adding a third aging treatment on properties of Incoloy 901

(e) Three tests.

(f) Solution treated at 1085 °C (1985 °F) for 2 h; water quenched; aged at 790 °C (1450 °F) for 2 h, air cooled; aged at 720 °C (1325 °F) for 24 h, air cooled; aged at 650 °C (1200 °F) for 12 h, air cooled.

(g) Two tests

Another example showing the effect of a stabilization treatment on rupture ductility is presented in Table 15. Initially, the heat treatment included a solution treatment at 1085 °C (1985 °F) for 2 h (air cooling) and aging at 720 °C (1325 °F) for 24 h (air cooling). The rupture ductility was significantly improved, with a small penalty in rupture life, by adding an 810 °C (1490 °F) stabilization treatment.

Table 15 Effect of revision in aging treatment on creep-rupture properties of Incoloy 901

Test No.	Creep rupture[(a)]			
	Original treatment[(b)]		Revised treatment[(c)]

6	76	4	84	**8**

(a) At 650 °C (1200 °F) and 552 MPa (80 ksi) specified minimum: life, 23 h: elongation, 5%.

(b) Solution treated at 1085 °C (1985 °F) for 2 h, cooled; aged at 720 °C (1325 °F) for 24 h, air cooled.

(c) Same conditions as in (b) except that temperature of first aging was 810 °C (1490 °F)

Inconel X-750 heat treatment in general depends on the application and the properties desired. For service above 595 °C (1100 °F), optimum properties in rods, bars, and forgings are achieved by:

- Solution treating at 1150 °C (2100 °F) for 2 to 4 h (air cooling)
- Stabilization treating at 845 °C (1550 °F) for 24 h (air cooling)
- Aging at 705 °C (1300 °F) for 20 h (air cooling)

This treatment maximizes creep and rupture strength.

For service below 595 °C (1100 °F), the optimum heat treatment is:

- Solution heat treating at 980 °C (1800 °F) for 1 h (air cooling)
- Aging at 730 °C (1350 °F) for 8 h (furnace cooling) to 620 °C (1150 °F)
- Hold for total time of 18 h and then air cool

This treatment maximizes tensile properties. Heat treatments for various product forms of Inconel X-750 are summarized in Table 16.

Table 16 Typical thermal treatments for precipitation hardening of Inconel X-750 products

Form	**Desired property**	Thermal treatment
Rods, bars, and forgings	Strength and optimum ductility up to 595 °C (1100 °F)	**Equalize: 885 °C (1625 °F), 24 h, air cool Precipitation: 705 °C (1300 °F), 20 h, air cool**

	Maximum creep strength above 595 °C (1100 °F)	**Full solution: 1150 °C (2100 °F), 2-4 h, air cool Stabilize: 845 °C (1550 °F), 24 h, air cool Precipitation: 705 °C (1300 °F), 20 h, air cool**
Sheet, strip, and plate	High strength at high temperatures	**Annealed + Precipitation: 705 °C (1300 °F), 20 h, air cool**
	High strength and higher tensile properties to 705 °C (1300 °F)	**Annealed + Furnace-cool, precipitation: 730 °C (1350 °F), 8 h, furnace cool to 620 °C (1150 °F), hold 8 h, air cool[(a)]**

Tubing	High strength at high temperatures	**Annealed + Precipitation: 705 °C (1300 °F), 20 h, air cool**
No. 1 temper wire	Service up to 540 °C (1000 °F)	**Solution treated + cold drawn (15-20%) + 730 °C (1350 °F), 16 h, air cool**
Spring temper wire	Service up to 370 °C (700 °F)	**Solution treated + cold drawn (30-65%) + 650 °C (1200 °F), 4 h, air cool**
	Service at 480-650 °C (900-1200 °F)	**Cold drawn (30-65%) + 1150 °C (2100 °F), 2 h, air cool + 845 °C (1550 °F), 24 h, air cool + 705 °C (1300 °F)). 20 h, air cool**

Source: Ref 7

(a) Equivalent properties in a shorter time can be developed by the following precipitation treatment: 760 °C (1400 °F)) for 1 h. furnace cool (FC) to 620 °C (1150 °F)). hold 3 h, air cool (AC).

Heat Treatment of Nickel-Iron-Base Alloys Strengthened by γ''. The heat treatment of nickel-iron-base superalloys strengthened by the γ'' phase are fashioned using many of the same principles that guide the heat treatments of A-286 and Incoloy 901. In these alloys, δ phase, which is present at temperatures above the γ'' solvus, can be used for grain size control, just as η phase can be utilized in A-286 or Incoloy 901. However, careful heat treatment is required to ensure adequate precipitation of γ'' instead of the δ(orthorhombic) phase of the same Ni_3Nb composition. The latter is invariably incoherent and does not confer strength when present in large quantities. In the absence of iron, or at temperatures and times shown in the transformation diagram of an iron-containing alloy (Fig. 4), the δ phase forms instead of the γ'' phase.

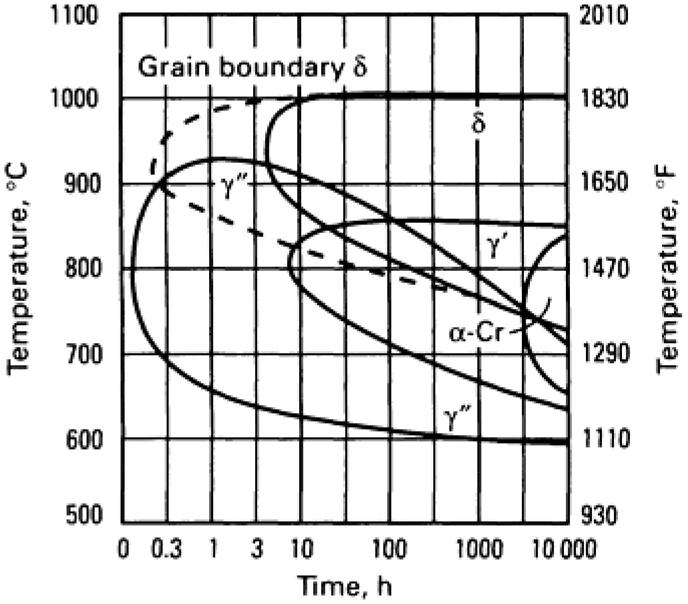

Fig. 4 Transformation diagram for vacuum-melted and hot-forged Inconel 718 bar. Source: Ref 8

The γ'' phase forms in alloys such as Inconel 718 and Inconel 706. In Inconel alloy 718, γ'' forms in the range of 705 °C (1300 °F) to 900 °C (1650 °F) and has a solvus temperature of about 910 °C (1675 °F). The δ phase, depending on exposure time (Fig. 4), precipitates in the approximate temperature range of 870 °C (1600 °F) to 1010 °C (1850 °F) and has a solvus temperature of about 1010 °C (1850 °F). The alloy can be worked and solution heat treated above the δ

solvus, or at a temperature below the δ solvus but above the γ'' solvus for grain size control. Gamma double prime often precipitates together with γ' in Inconel 718 (Fig. 4), but γ'' is the principal strengthening phase under such circumstances. Unlike γ', which causes strengthening through the necessity to disorder the particles as they are sheared, γ'' strengthens by virtue of high coherency strains in the lattice. More detailed descriptions of the physical metallurgy of γ'/γ'' alloys appear in Volume 1 of *ASM Handbook*, formerly 10th Edition *Metals Handbook.*

Heat Treatment of Inconel 718. Inconel 718 is usually used in the solution and aged condition; the exact conditions of the temperatures, times, and cooling rates depend on the application and mechanical property needs. Many aerospace applications requiring high tensile and fatigue strength, as well as good stress-rupture properties, use a solution treatment below the δ solvus and a two-step aging treatment as follows:

- Solution heat treat at 925 to 1010 °C (1700 to 1850 °F) for 1 to 2 h (air cooling or faster)
- Age at 720 °C (1325 °F) for 8 h followed by furnace cooling to 620 °C (1150 °F)
- Hold at 620 °C (1150 °F) for a total aging time of 18 h (air cooled)

Higher strength levels are achieved by forging below the δ solvus, quenching after forging, and performing the two-step aging process directly without a solution treatment. This approach, termed direct aging, requires high quality, uniform billet material, and careful control of the forging process to achieve the high strengths and the uniform ASTM 10 grain size throughout the forging.

The effect of the solution temperature, or direct aging (no solution treatment), on tensile and stress-rupture properties of Inconel 718 is shown in Table 17. The highest tensile strength is achieved with the direct-aged material, at some sacrifice of stress-rupture life. The lower solution temperatures produce better strength, while the higher solution temperatures (up to 1010 °C, or 1850 °F) result in better stress-rupture strength.

Table 17 Properties of Inconel 718 as function of heat treatment

Solution treatment[(a)]	**0.2% yield strength**		Room-temperature tensile properties

Typical properties for Inconel 718 in three forms are plotted as a function of temperature in Fig. 5. The standard solution-treated and aged condition of Inconel 718 with an average grain size of ASTM 4 to 6 is labeled STD 718. This material condition is used for noncritical or difficult-to-make shapes. High-strength 718, labeled HS 718, with ASTM 8 average grain size, is used for more highly stressed components with less complex configurations. This material is also solution-treated and aged, but tighter controls are placed on input billet material and the forging practice. The highest strengths and fatigue properties are achieved by Inconel 718 in the direct-aged condition, termed DA 718, with ASTM 10 average grain size. Figure 5(b) again illustrates that these strengths are obtained at some reduction of stress-rupture life at low stress and high temperature. To obtain the DA 718 properties in Fig. 5, very high-quality and uniform input material is required along with tightly controlled forging temperatures and processing.

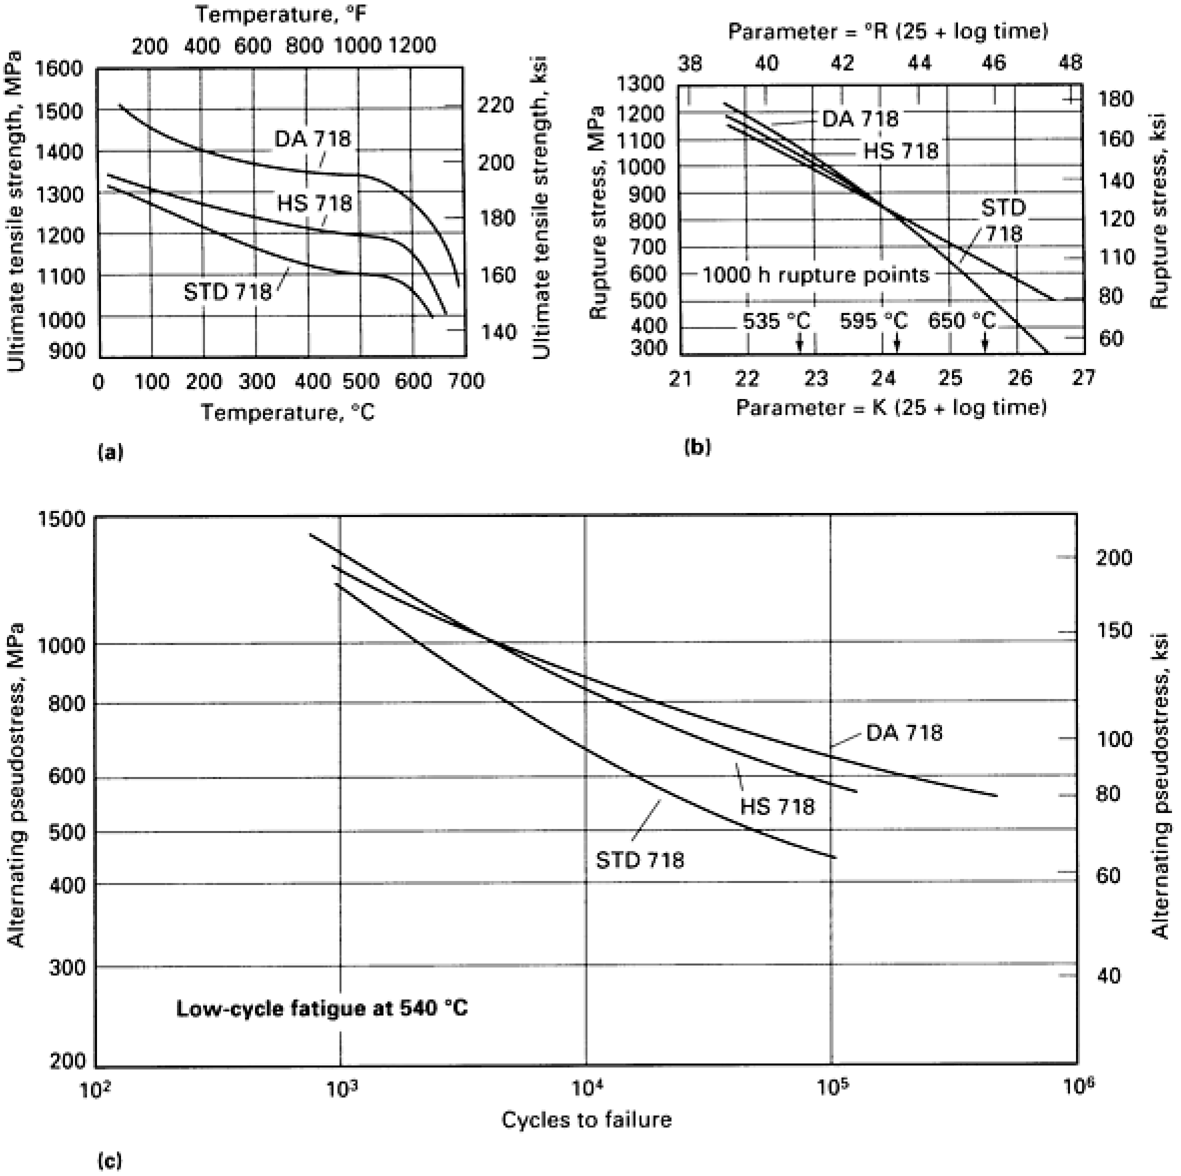

Fig. 5 Typical properties of Inconel 718 as a function of processing. (a) Ultimate tensile strength. (b) Rupture stress. (c) Fatigue at 540 °C (1000 °F). Source: Ref 1

A slightly different solution-and-age heat treatment is sometimes used for optimum ductility, impact properties, and low-temperature toughness in heavy sections, although it can also produce notch brittleness in stress rupture. This heat treatment involves:

- Solution heat treatment at 1040 to 1065 °C 1900 to 1950 °F) for $\frac{1}{2}$ to 1 h, air cooled (or faster)
- Aging at 760 °C (1400 °F) for 10 h with furnace cool to 650 °C (1200 °F)
- Hold at 650 °C (1200 °F) for a total aging time of 20 h (air cool)

Tensile properties as a function of the two heat treatment approaches are listed in Table 18 for hot-rolled rounds of various diameters and in Table 19 for pancake forgings.

Table 18 Tensile properties in longitudinal orientations of Inconel 718 hot-rolled rounds of several sizes and in various heat-treated conditions

For applications of Inconel 718 in the oil and gas industry, the very high strength levels needed in aerospace applications are unnecessary. Instead, heat treatments are designed to address other needs, including good toughness with adequate strength and resistance to hydrogen embrittlement and stress-corrosion cracking. Single-step aging treatments are used to develop mechanical properties in oil and gas applications. Solution treatment in the range of 1010 to 1065 °C (1850 to 1950 °F) is followed by a single-step aging at 650 to 815 °C (1200 to 1500 °F). Room-temperature properties achieved by single-step and two-step aging treatments are compared in Table 20. The single-step aging treatments result in lower strengths but higher fracture toughness. Both general and pitting corrosion resistance can be reduced at higher aging temperatures. This behavior has been attributed to carbide formation and chromium depletion in localized areas. The trade-off between strength and toughness is illustrated in Fig. 6, which shows yield strength and toughness as a function of aging temperature for material after solution-and-age treatment. The exact choice of heat treatment parameters depends on the balance of properties required.

Table 20 Effect of heat treatment on typical room-temperature properties of Inconel 718

Precipitation-Strengthened Nickel-Base Superalloys

To achieve optimal microstructures for the intended applications, wrought precipitation-strengthened nickel-base superalloys usually receive a solution heat treatment stage followed by one or more precipitation aging heat treatments. The solution heat treatment may be above or below the γ' solvus temperature depending on a number of factors, including intended grain size, whether strengthening from warm working is to be retained, the desired γ' morphology, and considerations of carbide precipitation. These microstructural goals are determined by the property requirements. Aging heat treatments are designed to precipitate γ' and control its volume fraction, size, morphology, and distribution. The aging heat treatments may also precipitate and stabilize various carbide phases and control their morphologies. The temperatures and times of aging heat treatments depend on the alloy composition and on the specific property goals.

The simplest heat treatment, for wrought alloys with relatively low alloying contents and low γ' volume fractions, is a high-temperature solution treatment followed by air or more rapid cooling, and then low-temperature aging. The solution heat treatment temperature is above the γ' solvus (thus dissolving γ' and possibly carbides, depending on the alloy) and causes recrystallization and grain growth to a desired size. The aging precipitates γ' homogeneously and $M_{23}C_6$ typically at grain boundaries. An example of this basic method for Nimonic 80A or Nimonic 90 is as follows:

- Solution heat treatment at 1080 °C (1975 °F) for 8 h and air cool
- Aging at 700 °C (1290 °F) for 16 h and air cool

The hardness changes as a result of aging Nimonic 80A at various temperatures after a solution exposure of 1080 °C (1975 °F) for h and water quenching are shown in Fig. 7. The curves exhibit normal precipitation hardening characteristics; the lower temperatures and longer aging times provide the highest hardnesses.

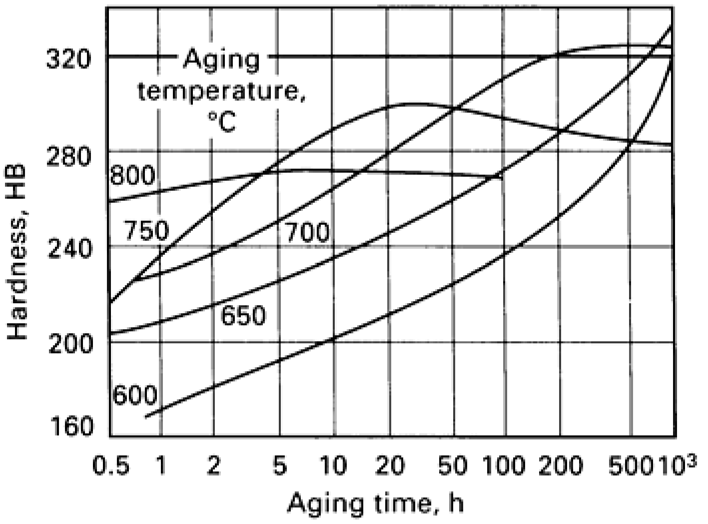

Fig. 7 Hardness changes on aging Nimonic 80A at various temperatures. Prior treatment: solution 1080 °C (1975 °F) for 8 h, water quenched. Source Ref 13

Heat treatment affects the types and morphologies of carbides and also the γ' morphology in more highly alloyed superalloys with higher γ' volume fractions. Consideration of these effects has led to modification of the above two-step (solution treat-and-age)treatments. In Nimonic 80A, the above two-step heat treatment yielded good tensile and short-time rupture properties, but did not stabilize the microstructure sufficiently to produce optimized properties for long-term elevated-temperature service. For a stabilized microstructure, a higher-temperature aging cycle of 850 °C (1560 °F) for 24 h (air cooling) was added before the final 700 °C (1290 °F) aging. The purpose of the stabilization treatment is to force the development of grain boundary $M_{23}C_6$ carbides by a reaction in which MC carbides react with matrix constituents to form $M_{23}C_6$ carbides and γ'. Thus, the stabilization aging heat treatment results in grain boundaries with coarse discrete $M_{23}C_6$ carbides surrounded by a layer of γ'. The stabilization of the grain boundary carbides led to better long-time (low stress, high temperature) stress-rupture properties as shown in Fig. 8.

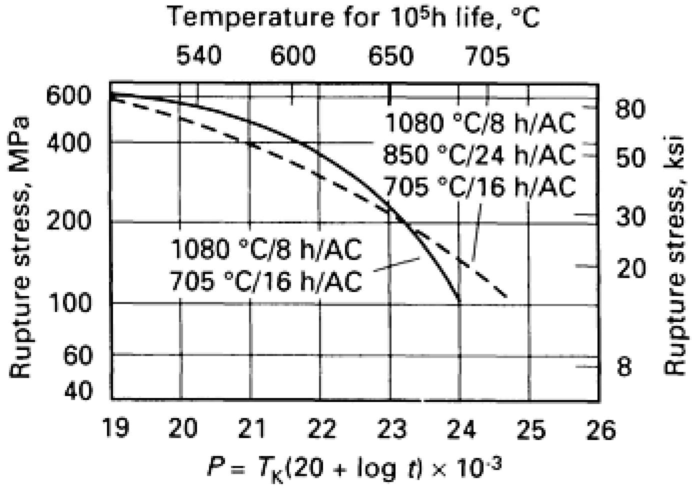

Fig. 8 Effect of increasing intermediate aging on rupture properties of wrought Nimonic 80A. AC, air cooled. Source: Ref 14

Carbide distributions can also be controlled by modifying the temperature for solution treatment. For example, a solution treatment of René 41 at 1175 °C (2150 °F) leads to precipitation of a grain-boundary film of $M_{23}C_6$, with deleterious effects on mechanical properties. Therefore, a lower solution treatment temperature (about 1075 °C, or 1970 °F) is used to

preserve the fine-grain as-worked structure with well-dispersed M_6C (Ref 15). With exposures of about 1075 to 1095 °C (1970 to 2000 °F) for 8 to 10 h, M_6C remains stable but γ' goes into solution (Fig. 9).

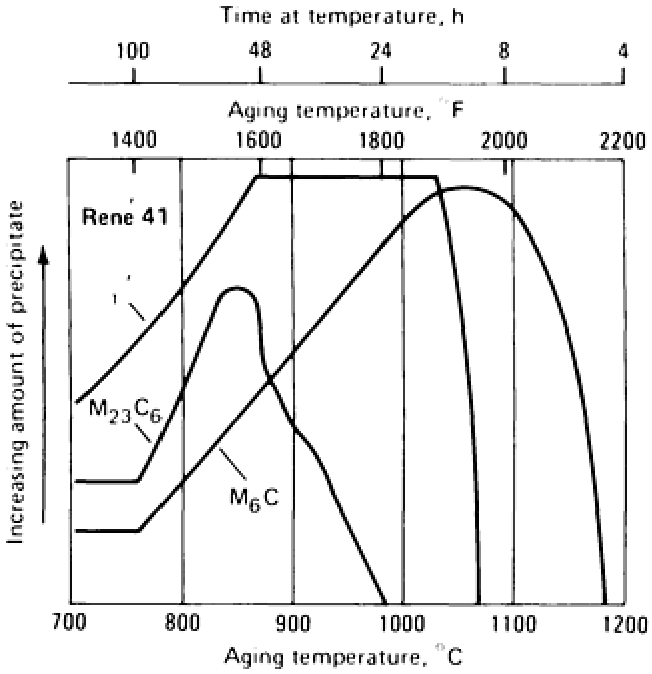

Fig. 9 Relative amounts of precipitates resulting from aging René 41 at various times and temperatures after solution treating at 1205 °C (2200 °F) and water quenching

Udimet 500 is typical of wrought precipitation-hardened superalloys that contain MC and $M_{23}C_6$ carbides and are strengthened by γ'. For a good balance of tensile strength and stress-rupture life, the alloy is given a stabilization treatment before final aging (see Example 2 in this article). If high room-temperature tensile properties are desired and stress-rupture requirements are less important, a two-step heat treatment consisting of just the 1080 °C (1975 °F) solution treatment and the 760 °C (1400 °F) age treatment may be utilized. Table 21 shows how the room-temperature tensile ductility and ultimate strength in Udimet 500 were improved by eliminating the 845 °C (1550 °F) stabilization treatment.

Table 21 Effect of eliminating intermediate aging on typical room-temperature mechanical properties of Udimet 500

	Ultimate tensile strength		**Yield strength (0.2% offset)**		**Elongation in 50 mm (2 in.), %**	Reduction in area, %
	MPa	**ksi**	**MPa**	**ksi**		
Specified min	1030	150	690	100	10	**15**
Obtained with intermediate aging[(a)]						
Test 1	1030	149	830	120	7	**11**
Test 2	970	141	810	118	4	**5**

Obtained without intermediate aging[(b)]

Test 2	**1230**	**179**	**850**	**123**	**14**	**16**

(a) Heat treatment: 4 h at 1080 °C (1975 °F), air cool; 24 h at 845 °C (1550 °F), air cool (intermediate aging); 16 h at 760 °C (1400 °F), air cool.

(b) Same as (a), but without intermediate aging

For optimum creep strength, an initial high-temperature solution treatment may be added to develop a coarser grain size. For Udimet 500, a four-step heat treatment includes an initial solution treatment at 1175 °C (2150 °F) for 2 h (with air cooling) followed by the three-step heat treatment described in Example 2 of this article.

Waspaloy is a widely used superalloy for which the heat treatment approach is similar to that for Udimet 500. The heat treatment temperatures and times vary according to working temperatures and microstructural goals. For applications (such as turbine disks) requiring fine grain structures for optimum tensile, stress rupture, and cyclic properties, a typical heat treatment is:

- Partial solution treatment below the γ' solvus at 995 to 1040 °C (1825 to 1900 °F) for 4 h with air cooling (or faster)
- Stabilization at 845 °C (1550 °F) for 4 h with air cooling
- Aging at 760 °C (1400 °F) for 16 h with air cooling

Before requirements for finer grain sizes led to the use of lower solution temperatures, higher solution temperatures and longer stabilization treatments were used. This was because the higher solution temperature more effectively dissolved carbides, and because a longer stabilization (for example, 845 °C, or 1550 °F for 24 h with air cooling) was required in order to restore sufficient ductility by spheroidizing the reprecipitating grain-boundary carbides. Now, the lower-temperature solution treatment starts the carbide precipitation process, and a shorter stabilization can be used.

The Waspaloy heat treatment for applications (such as turbine blades) requiring better creep resistance (and therefore a coarser grain size) involves a higher solution temperature above the γ' solvus and a longer stabilization exposure. For turbine blade applications, Waspaloy typically receives:

- 1080 °C (1975 °F) for 4 h with air cooling (or faster)
- 845 °C (1550 °F) for 24 h with air cooling
- 760 °C (1400 °F) for 16 h with air cooling

Figure 10 illustrates the effect of the different heat treatments on the tensile and stress-rupture properties of Waspaloy. A disk heat treatment yields better tensile and rupture properties at lower temperatures. The blade heat treatment results in better rupture strength at higher temperatures.

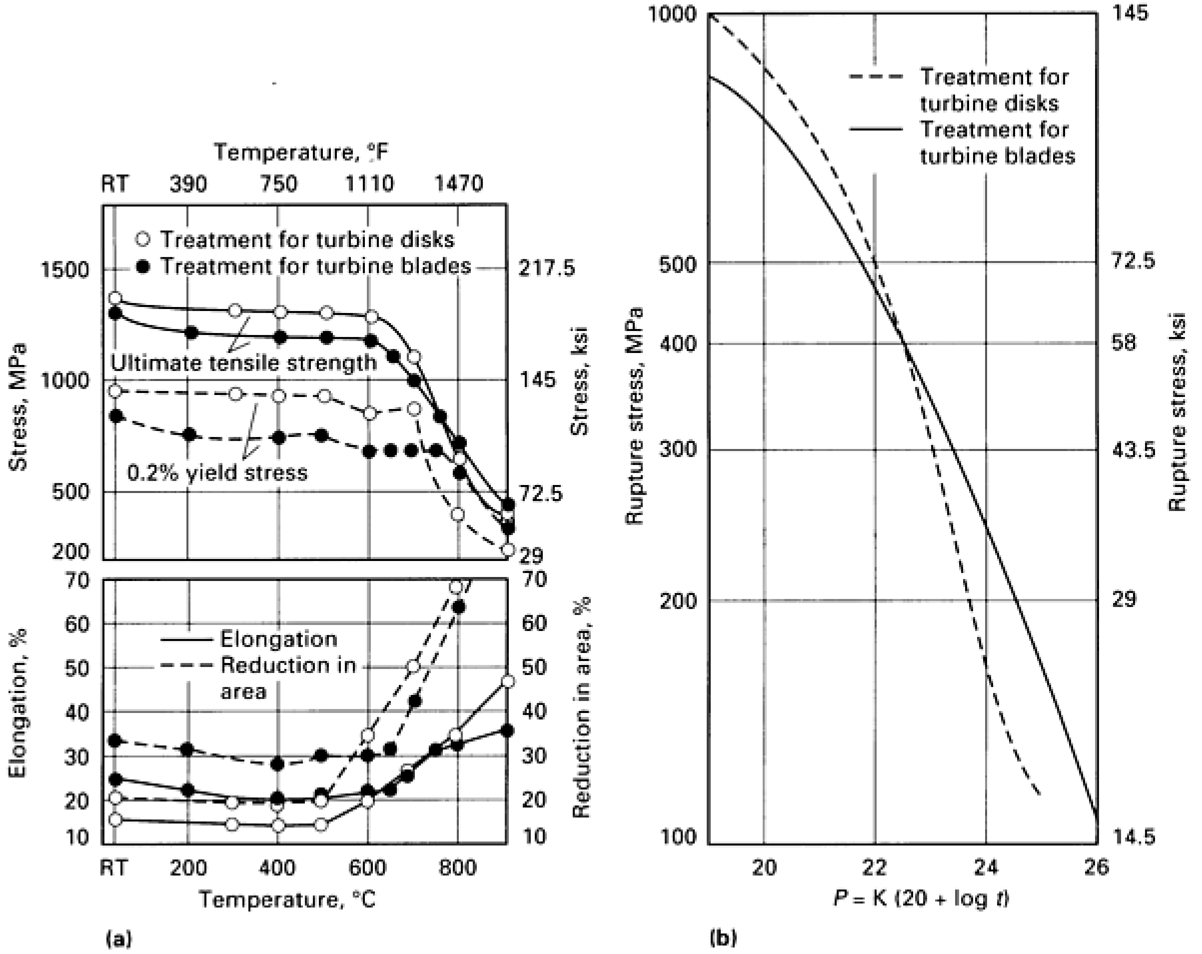

Fig. 10 Influence of different treatments on (a) the tensile properties of Waspaloy and (b) the Larson-Miller plot of Waspaloy. Source: Ref 16

Udimet 700 (or Astroloy, which is very similar) and Udimet 710 are examples of more highly alloyed wrought superalloys with a relatively high μ' volume fraction of about 40%. Different heat treatments are administered depending on whether a coarse-grained microstructure for turbine bucket and vane applications is desired, or a fine-grained microstructure for disk applications. For a coarse-grained microstructure the following heat treatment is typical:

- 1175 °C (2150 °F) for 4 h with air cooling
- 1080 °C (1975 °F) for 4 h with air cooling
- 845 °C (1550 °F) for 24 h with air cooling
- 760 °C (1400 °F) for 16 h with air cooling

The 1175 °C (2150 °F) annealing is a full-solution treatment above the γ' solvus that dissolves the precipitate and allows the grains to coarsen. During the 1080 °C (1975 °F) aging exposure, about half of the γ' that is ultimately formed precipitates and forms a coarse dispersion of particles 0.2 to 0.6 μm in diameter. The two subsequent aging heat treatments build precipitates of fine γ' between the coarser γ' particles, and also precipitate $M_{23}C_6$ at grain boundaries. This heat treatment yields an average grain size of about 225 μm with γ' volume fraction of about 45%. The coarse-grained structure is tailored for good creep-rupture strength.

For a fine-grained microstructure the heat treatment is of the following form:

- 1105 °C (2020 °F) for 4 h with air cooling (or faster)
- 870 °C (1600 °F) for 8 h with air cooling

- 980 °C (1800 °F) for 4 h with air cooling
- 650 °C (1200 °F) for 24 h with air cooling
- 760 °C (1400 °F) for 8 h with air cooling

The 1105 °C (2020 °F) anneal is a partial solution treatment below the γ' solvus that retains some of the γ' to limit grain growth. The subsequent treatments precipitate carbides and γ'. The two-step exposures of first 870 °C (1600 °F) and then 980 °C (1800 °F) are designed to maximize first the nucleation of precipitates and then the rate of growth of the precipitates. The average grain size of the structure produced is about 11 μm with a γ' volume fraction of about 35%. The fine-grained structure has better mechanical properties at turbine disk application temperatures than that from coarse-grained heat treatment, which is designed for higher-temperature applications.

The effect of the amount of cold working on the recrystallization and grain growth during subsequent solution treating of the nickel-base superalloy Nimonic 90 is shown in Fig. 11. The effect is similar to the behavior shown for A-286 in Fig. 1. The critical amount of deformation that leads to abnormally large grains is in the range of 2 to 10% reduction in thickness, and the grain growth accelerates rapidly at temperatures above 1100 °C (2010 °F).

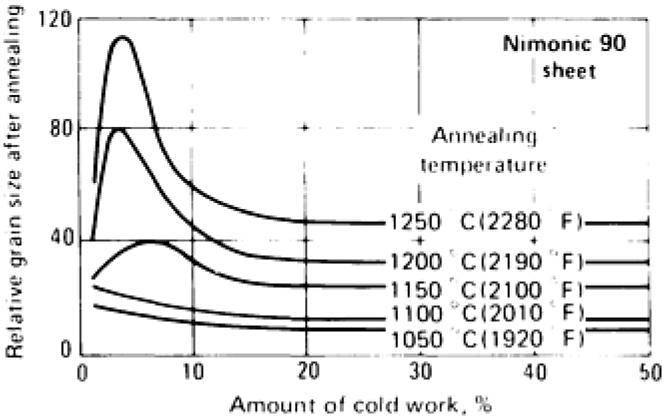

Fig. 11 Effect of cold work and annealing on grain size for Nimonic 90 sheet cold rolled in steps from 1.8 to 0.9 mm (0.072 to 0.036 in.) thick and annealed at five temperatures

The precipitation-hardened superalloys that undergo extensive deformation processing, as in sheet forming, usually require in-process annealing to maintain temperatures, relieve forming stresses, and enhance microstructural changes. The annealing practice can also have a marked effect on response to solution treating and aging. This is illustrated by the following two examples for René 41. Like solution-treatment temperatures (Fig. 9), high annealing temperatures can dissolve M_6C carbides, which are useful in preventing formation of $M_{23}C_6$ grain boundary films during aging.

Example 4: Effect of Annealing Temperature on the Grain-Boundary Carbides and Ductility of René 41 Sheet.

In one case, parts formed from René 41 sheet showed strain age cracking after solution treatment at 1080 °C (1975 °F) for $\frac{1}{2}$ h, air cooling, and then aging at 760 °C (1400 °F) for 16 h. Cracking has been attributed to a carbide network in the grain boundaries. Cause of the carbide network was traced to in-process annealing at 1180 °C (2150 °F). At 1180 °C (2150 °F) the M_6C carbide was dissolved. Subsequent exposure to temperatures between 760 and 870 °C (1400 and 1600 °F) produced an $M_{23}C_6$ carbide network in the grain boundaries that reduced ductility to an unacceptable level. If the annealing temperature is kept below 1095 °C (2000 °F), M_6C does not dissolve (Fig. 9) and ductility can be improved. A similar effect can occur in weldments of nickel-base alloys if they are annealed at temperatures above 1095 °C (2000 °F).

Example 5: Effect of Thermomechanical Processing on the Grain-Boundary Carbides and Ductility of René 41 Bar Stock.

A problem similar to that described in the preceding example occurred in René 41 bar stock. Grain-boundary carbide network reduced ductility and caused difficulty (sometimes cracking) during forming and welding. Investigation of the cause of the grain-boundary network indicated that the bar stock was produced with a final rolling temperature of 1180 °C (2150 °F). Light reductions were taken during final rolling to ensure proper size for the finished bar stock and to eliminate the possibility of surface tearing. This high rolling temperature, coupled with relatively light reductions (in the range of 2 to 3%), produced grain-boundary network because:

- The M_6C carbides were dissolved at the rolling temperature
- Slow cooling through the range of 870 to 760 °C (1600 to 1400 °F) produced $M_{23}C_6$ in an unfavorable morphology (grain-boundary carbide film)

Rolling temperatures of 1150 °C (2100 °F) maximum, coupled with a final reduction in rolling of at least 10 to 15%, eliminated the grain-boundary carbide film and produced bars that could be welded and formed.

Solid-Solution-Strengthened Iron-, Nickel- and Cobalt-Base Superalloys

Solid-solution-strengthened iron-, nickel-, and cobalt-base superalloys are generally distinguishable from the precipitation-strengthened superalloys by their relatively low content of precipitate-forming elements such as aluminum, titanium, or niobium. There are, of course, some exceptions to this, particularly as regards niobium content. Typical compositions for precipitation-strengthened and solid-solution-strengthened superalloys are given in Table 1.

As their classification implies, these alloys derive a significant proportion of their strength from solution strengthening, most typically associated with a high content of refractory metals, such as molybdenum or tungsten. Not to be overlooked, however, is the equally significant contribution of carbon, which serves both as a potent solution-strengthening element, and as a source of both primary and secondary carbide strengthening. Primary carbides, carried over from final melting operations, serve to control grain structure and thus contribute somewhat to alloy strength; however, the formation of secondary carbides, which is critical to developing the best strength, is also the key issue in formulating and performing alloy heat treatments.

Solid-solution-strengthened superalloys are usually supplied in the solution-heat-treated condition, where virtually all of the secondary carbides are dissolved, or "in solution." Microstructures generally consist of primary carbides dispersed in a single-phase matrix, the grain boundaries of which are reasonably clean. This is the optimum condition for good elevated-temperature strength and generally best room-temperature fabricability. When the carbon is mostly in solution, exposure at elevated temperatures below the solution temperature will result in secondary carbide precipitation. In service, where the alloy component is subjected to operating stresses, this carbide precipitation will occur both on grain boundaries and intragranularly on areas of high dislocation density. It is the latter that provides for increased strength in service. When exposure to temperatures below the solution temperature occurs during component heat-treating cycles, the result is usually to precipitate secondary carbides only on grain boundaries. This is not normally beneficial for subsequent fabrication, and it reduces the capability of the alloy to develop in-service strengthening by depleting carbon from solution.

Generally speaking, then, solid-solution-strengthened alloy components will exhibit highest strength when placed in service in the fully solution-heat-treated condition; however, the reality of modern complex component designs dictates what can and cannot be done in terms of final heat treatments. Quite often the compromise between component manufacturability and performance will mean something less than optimal alloy structure.

Annealing and Stress Relieving. In the case of solid-solution-strengthened superalloys, heat treatments performed at temperatures below the secondary carbide solvus or solutioning temperature range are classified as mill annealing or stress-relief treatments. Mill annealing treatments are generally employed for restoring formed, partially fabricated, or otherwise as-worked alloy material properties to a point where continued manufacturing operations can be performed. Such treatments may also be used in finished raw materials to produce structures that are optimum for specific forming operations, such as fine grain size structure for deep drawing applications.

Mill-annealed products may also be used in preference to solution heat treatments for final components where properties other than creep and stress-rupture strength are vital. For example, where low-cycle fatigue properties are important, mill annealing may be used to produce a finer grain size. A finer grain size from mill annealing may also be useful in applications where yield strength instead of creep strength is the limiting design criterion. Finally, mill annealing may be

selected in preference to solution annealing because of external constraints, such as avoidance of component distortion at full solution annealing temperatures, or limits to temperature imposed by the melting point of component braze joints.

Because mill annealing is performed below the secondary carbide solvus temperature, some decoration of grain boundaries can be expected in the microstructure. Depending upon the annealing temperature, the particular alloy, and the nature of the secondary carbide involved, this decoration may take the form of either discrete, globular particles or a more continuous film-like morphology. Cooling rates will markedly influence the appearance of this carbide precipitation, as most alloys of this type exhibit the most significant amount of precipitation in the temperature range from about 650 to 870 °C (1200 to 1600 °F). It is always recommended that components be cooled as rapidly as is feasible through this range, within the constraints of equipment used and with due consideration to avoiding component distortion from thermal stresses.

Typical minimum mill annealing temperatures for various alloys are given in Table 22. These temperatures vary significantly from alloy to alloy. They are based principally upon the ability of the treatment to develop a recrystallized grain structure starting from a cold-worked or warm-worked condition and to produce low enough yield strength and high enough ductility for subsequent cold forming operations. Grain size would be expected to increase somewhat, although perhaps not markedly, when higher mill annealing temperatures are used.

Table 22 Minimum mill annealing temperatures for solid-solution-strengthened alloys

Alloy	Approximate minimum temperature for mill annealing	
	°C	°F
Hastelloy X	1010	**1850**
Hastelloy S	955	**1750**
Alloy 625	925	**1700**
RA 333	1035	**1900**
Inconel 617	1035	**1900**
Haynes 230	1120	**2050**
Haynes 188	1120	**2050**
Alloy L-605	1120	**2050**
Alloy N-155	1035	**1900**

The same basic temperatures would apply for mill annealing hot-worked material, although solution annealing is more common. Hot-worked material is usually dynamically recrystallized during the hot-working operation, and the main effect of mill annealing is to promote uniformity of the structure throughout the piece.

Times at temperature required for mill annealing are governed by several factors. Sufficient furnace time should be allowed to ensure that all parts of the piece are at temperature for the requisite time. The requisite time should be long enough to ensure that structure changes, such as recovery, recrystallization, and carbide dissolution (if any), are essentially complete. Generally, about 5 to 20 min at temperature is sufficient, particularly in thin sections. In continuous thin-strip annealing operations, as little as 1 to 2 min will often suffice. Excessive time at temperature for mill annealing is not necessarily deleterious, but is most often not beneficial. Use of a thermocouple on the actual piece undergoing annealing is always appropriate.

Stress Relief. Unlike mill annealing, stress-relief treatments for solid-solution-strengthened superalloys are not well defined. Dependent upon the particular circumstances, stress relief may be achieved with relatively low-temperature annealing, or may require the equivalent of mill or even solution annealing. In any case, such treatments represent a major compromise between the effectiveness of stress relief and the harm done to the structure or dimensional stability of the component.

Strictly speaking, stress-relief annealing should be considered only if the material is not recrystallized by the treatment. If the intent is to relieve stresses in a piece or component that would otherwise be mill annealed or solution treated, then the first choice is the equivalent of a solution heat treatment or mill annealing to accomplish the required stress relief. Temperatures below the mill annealing temperature range, particularly in the range of 650 to 870 °C (1200 to 1600 °F), will likely result in significant carbide precipitation, or other phase formation in some alloys, which may significantly impair alloy performance. Treatments below 650 °C (1200 °F) may be less deleterious, but are likely to be less effective in relieving residual stresses.

To relieve stresses in a partially cold- or warm-worked piece or component (that is, a finish-formed component that cannot be mill- or solution-annealed), then the stress-relief treatment should be restricted to a temperature less than that which will induce recrystallization. In this class of material, that temperature will vary with the particular alloy and degree of cold or warm work, but will generally be less than about 815 °C (1500 °F). In some materials (such as Inconel 625 and Haynes alloy 214), age-hardening reactions occurring at these lower temperatures must be considered in addition to the more general carbide precipitation encountered in other alloys.

Times at temperature required to effect a significant amount of stress relief are equally ill-defined. For the equivalent to mill and solution annealing, similar times should be used. For lower-temperature stress-relief treatments, no specific guidelines are offered, but excessive times should be avoided for obvious reasons.

Solution heat treating is the most common form of finishing operation applied to solid-solution-strengthened superalloys. As mentioned earlier, a solution treatment places virtually all the secondary carbides into solution. The temperatures at which all secondary carbides are dissolved vary somewhat what from alloy to alloy, and can differ as a function of the type of secondary carbide involved and the carbon content.

Typical solution treatment temperatures for various alloys are given in Table 23. For some alloys the temperature range is broader than others; in most cases, such as Haynes 230, this is related to desired flexibility in controlling the grain size in the solution-treated piece. In Haynes 230, for example, an 1175 °C (2150 °F) solution treatment might produce an ASTM grain size between 7 and 9, while a solution treatment at 1230 °C (2250 °F) could be expected to yield a grain size of ASTM 4 to 6, assuming starting material in a sufficiently cold-reduced condition.

Table 23 Typical solution annealing temperatures for solid-solution-strengthened alloys

Alloy	Typical solution annealing temperatures	
	°C	°F
Hastelloy X	1165-1190	**2125-2175**
Hastelloy S	1050-1135	**1925-2075**

RA 333	1175-1205	**2150-2200**
Inconel 617	1165-1190	**2125-2175**
Haynes 230	1165-1245	**2125-2275**
Haynes 188	1165-1190	**2125-2175**
Alloy L-605	1175-1230	**2150-2250**
Alloy N-155	1165-1190	**2125-2175**
Haynes 556	**1165-1190**	2125-2175

Recrystallization and Grain Size. A major function of the solution annealing treatment is to recrystallize warm- or cold-worked structure fully and to develop the required grain size. Aspects such as heating rate and time at temperature are important considerations. Rapid heating to temperature is usually desirable to help minimize carbide precipitation and to preserve the stored energy from cold or warm work required to provide recrystallization and/or grain growth during the solution treatment itself. For much the same reason that re-solution-treating an already annealed piece often does not coarsen grain size without increasing the temperature, slow heating of a cold- or warm-worked material to the solution-treating temperature can produce a finer grain size than may be desired or required.

Time at temperature considerations for solution heat treatments are similar to those for mill annealing, although slightly longer exposures are generally indicated to ensure full dissolution of secondary carbides. For minimum temperature solution treatments, heavier sections should generally be exposed at temperature for about 10 to 30 min, thinner sections for somewhat shorter times. Solution treatments at the high end of the prescribed temperature range can be shorter, similar to mill annealing. Although very massive parts, such as forgings, may benefit from somewhat longer times at temperature, in no case should any component be exposed to solution treatment temperatures for excessive periods (such as overnight). Long exposures at solution treatment temperatures can result in partial dissolution of primary carbides, with consequent grain growth or other adverse effects.

The effects of cooling rate upon alloy properties following solution heat treatment can be much more pronounced than those related to mill annealing. Because the solution treatment places the alloy in a state of greater supersaturation relative to carbon, the propensity for carbide precipitation upon cooling is significantly increased over that for mill annealing. It is therefore even more important to cool from the solution treatment temperature as fast as possible, bearing in mind the constraints of the equipment, and the need to avoid component distortion due to thermal stresses. The sensitivity of individual alloys to property loss from slower cooling down to about 650 °C (1200 °F) varies, but most alloys will suffer at least some property degradation as a result of secondary carbide precipitation. This is shown by the data in Table 24, in which the effects of various cooling practices on the low-strain creep properties of three alloys are described.

Table 24 Cooling rate effects on time to 0.5% creep at 870 °C (1600 °F) with 48 MPa (7 ksi) load

Solution treat at 1175 °C (2150 °F) and cool at the rate indicated	Time to 0.5% creep, h		
	Hastelloy X	**Haynes 188**	lnconel 617

Water quench	8	148	**302**
Air cool	7	97	**15**
Furnace cool to 650 °C (1200 °F) and then air cool	**6**	**48**	**9**

Solution Treating Combined with Brazing. Unlike mill annealing, which is usually performed as a manufacturing step itself, solution treating may sometimes be combined with another operation, which imposes significant constraints upon both heating and cooling practices. A good example of this is vacuum brazing. Often performed as the final manufacturing step in the fabrication of components, such a process precludes subsequent solution treatment by virtue of the limits imposed by the melting point of the brazing compound. Therefore, the actual brazing temperatures are sometimes adjusted to allow simultaneous solution heat treating of the component. Unfortunately, the nature of vacuum brazing furnace equipment specifically, and vacuum furnace equipment in general, is such that relatively slow heating and cooling rates are a given. In these circumstances, even with the benefit of advanced forced gas cooling equipment, the structure and properties of alloy components are likely to be less optimal than those achievable with solution treatments performed in other types of equipment.

Relationship of Processing History to Heat Treatment. As for most other alloy materials, the response of solid-solution-strengthened superalloys to heat treatment is very much dependent upon the initial material condition. Generally speaking, when the material is not in the cold- or warm-worked condition, the principal response to heat treatment is a change in the amount and morphology of secondary carbide phases present. Relief of minor residual stresses, or relaxation of internal strains, either of which may influence alloy properties to some degree, may also occur. Grain structure, however, may often be substantially unaltered by heat treatment when cold or warm work is absent.

Hot-worked products, in particular those produced at high finishing temperatures, undergo recovery, recrystallization, and grain growth during the working operation itself. If finish working temperatures are too high relative to the final mill-annealing or solution-treatment temperatures, a significant degree of control over the structure resides in the working operation, rather than in the heat treatment. Similarly, if the final hot-working reductions are small, the piece to be heat treated often is initially nonuniform and responds nonuniformly to heat treatment. Material finished at a very high temperature may be best heat treated at temperatures near the high end of the allowable range, and almost always at a temperature above the finish hot-working temperature. For cases with small finish reductions, temperatures at the low end of the range would probably be advisable to minimize the nonuniformity in structure. This last approach might be particularly advisable for pieces with very heavy section thickness, such as large forgings, large-size bars, and thick plates.

Fortunately, solid-solution-strengthened superalloys as a group exhibit relatively wide hot-working ranges, which allow finishing temperatures low enough to produce a warm-worked condition. They are also readily manufactured using cold working processes. In the warm-worked or cold-worked condition, grain structure control resides basically in the heat treatment, but results can be significantly influenced by the amount of work in the piece. As an example of this, the data presented in Table 25 show the influence of initial cold work on the grain size of final heat-treated Haynes 556 sheet.

Table 25 Effect of cold reduction and annealing temperature on grain size of 556 alloy

Cold reduction, %	**5-min subsequent annealing temperature**		**Degree of recrystallization**	ASTM grain size
	°C	**°F**		
0	None	None	. . .	**5.0-6.0**

40	1175	2150	Full	**4.5-6.5**
50	**1175**	**2150**	**Full**	**5.5-6.0**

The particular sequence of cold-work/annealing cycles used in multistep material manufacturing or component fabrication can also affect the structure and properties of these alloys. One general guideline is to keep the temperatures used for intermediate annealing steps at or below the final annealing temperature. Intermediate annealing at temperatures above the final annealing temperature can reduce the degree of structure control possible in the alloy.

The minimum level of cold work shown in Table 25, 10%, is an important rough dividing line between normal recrystailization behavior and possible abnormal grain growth in these alloys. Introduction of small amounts of cold or warm work prior to solution heat treating should be avoided where possible to minimize the potential for abnormal grain growth phenomena. The effects of very small amounts of cold work on the grain size response to annealing for Hastelloy X are shown in Table 26. The samples used to generate these data were carefully strained tensile test specimens, subsequently exposed to the annealing temperatures shown. Strains from 1 to 8% produced little effect for mill annealing temperatures up to 1120 °C (2050 °F); however, for solution annealing at 1175 °C (2150 °F), abnormal grain growth was observed for strains of 1 to 5%.

Table 26 Effect of small strains on abnormal grain growth of Hastelloy X

Prior cold work,%	**5-min subsequent annealing temperature**		ASTM grain size
	°C	**°F**	
0	None	None	**4.5-6.5**
1	1120	2050	**4.5-6.5**
2	1120	2050	**4.0-6.5**
3	1120	2050	**4.0-6.0**
4	1120	2050	**3.5-6.0**
5	1120	2050	**3.5-6.0**
8	1120	2050	**3.5-6.0**
1	1175	2150	**5.0 + 0 at surface**
2	1175	2150	**5.0-5.5 + 0 at surface**
3	1175	2150	**00-4.5**
4	1175	2150	**4.5-5.0 + 1.0-1.5**
5	1175	2150	**3.0-3.5 + 1.0-1.5 4.5-5.0**

8	**1175**	**2150**	**(recrystallized)**

Unfortunately, in everyday fabrication of complex components, it is difficult if not impossible to avoid situations where such low levels of cold work or strain are present. Some alloys are more tolerant of this than others, but virtually all will exhibit abnormal grain growth under some conditions. Procedures that may be effective for minimizing the problem are:

- Solution treating at the low end of allowable temperature ranges
- Mill annealing in preference to solution annealing for intermediate heat treatments during component fabrication
- Stress-relief annealing directly prior to final solution annealing

Cast Superalloy Heat Treatment

Heat treatment of cast superalloys in the traditional sense was not employed until the mid-1960s. Before the use of shell molds, the heavy-walled investment mold dictated a slow cooling rate with its associated aging effect on the casting. As faster cooling rates with shell molds developed, the aging response varied with section size and the many possible casting variables. These factors, coupled with significant γ' alloying additions, provided the opportunity to minimize property

scatter by heat treatment. The combination of hot isostatic pressing (HIP) plus heat treatment has also greatly enhanced properties.

Generally, heat treating cast superalloys involves homogenization and solution heat treatments or aging heat treatments. A stress-relief heat treatment may also be performed to reduce residual casting, welding, or machining stresses. Cobalt-base alloy heat treatments may be done in an air atmosphere unless unusually high-temperature treatments are required, in which case vacuum or inert gas environments are used. Conversely, nickel-base alloys are always heat treated in a vacuum or in an inert gas medium. Detailed information can be found in Ref 17.

Like wrought superalloys, the solution heat-treating procedures of cast superalloys must be optimized to stabilize the carbide morphology. High-temperature exposure may cause extensive carbide degeneration, resulting in grain-boundary carbide overload and compromised mechanical properties. Unlike wrought superalloys, however, many polycrystalline materials are used in the as-cast plus aged condition without any specific solution step. Cast cobalt-base superalloys, for example, are not usually solution treated (although they may be given stress-relief and/or aging treatments). When required, cast cobalt-base superalloys are generally aged at 760 °C (1400 °F) to promote formation of discrete $Cr_{23}C_6$ particles. Higher-temperature aging can result in acicular and/or lamellar precipitates.

Precipitation-strengthened nickel- or iron/nickel-base superalloys are cast using the investment casting process. The resultant casting comprises a large number of grains and is referred to as a polycrystalline or conventional casting. If the casting is solidified under a thermal gradient, a columnargrained directionally solidified casting will result. Directionally solidified (DS) airfoil castings are used in the turbine sections of gas turbine engines to enhance durability and performance. Additional benefits can be achieved using directional-solidification investment casting to cast turbine airfoils as single crystals. Precipitation-strengthened nickel-base superalloys are primarily utilized for turbine airfoils, while iron-nickel alloys are employed as large investment-cast structural castings.

Superalloys are heat treated to control the morphology of the precipitating phases (γ', γ'', carbides, and δ) that are responsible for the mechanical properties of the alloy. Three basic heat treatment steps are used:

- Solution
- Stabilization
- Aging

Representative heat treatments for several alloys are listed in Table 27.

Solution Treating. Polycrystalline cast nickel-base superalloys may or may not be given solution treatment. Because alloys respond differently to γ' solution treatment, some are only given an aging treatment. For those that do respond to partial solution treatment, the treatment is performed at a temperature safely below the incipient melting point of the alloy for times ranging from 2 to 6 h at temperature. The solution heat treatment is employed to dissolve the phases in the as-cast microstructure, in the ideal case returning the alloy microstructure to a single-phase γ(fcc) solid solution, and to homogenize the segregated as-cast microstructure.

The solution treatment is performed at a temperature above or near the γ' solvus temperature. A protective atmosphere, such as vacuum, argon, helium, or hydrogen, can be used to prevent oxidation of the casting. When a vacuum furnace is employed a partial pressure of an inert gas, such as argon, is used rather than a hard vacuum to prevent surface depletion of chromium and aluminum from the castings. When the solution heat treatment temperature is very close to the incipient melting temperature of the alloy, varied heating rates are used to homogenize the castings during the time taken to reach the solution temperature. This is done to prevent incipient melting, which might occur if a segregated casting were heated very rapidly. Many conventionally cast (polycrystalline) nickel-base alloys are not solution heat treated, but all directionally solidified alloys, either columnar-grained or single-crystal castings, are solution treated.

Gamma prime and other phases precipitate as the casting is cooled below the γ' solvus. In nickel-base superalloys, such as those used for turbine airfoils, growth of the fine γ' precipitate phase is very rapid at a few hundred degrees Fahrenheit below the high temperature involved in solution heat treatment. Therefore, it is necessary to cool the casting as rapidly as possible to prevent coarsening of the γ' during the cooling cycle, which can degrade the mechanical properties of the casting. Rapid cooling rates are achieved in a vacuum furnace by introducing additional cold inert gas and circulating the gas in the furnace. This is sometimes referred to as a gas furnace quench (GFQ). A retort, which contains the castings in a protective gas environment, is employed when a conventional furnace (not vacuum) is used for solution heat treatment. Removing the retort from the furnace and passing cold gas through it provides the desired rapid cooling rate. With iron-nickel-base alloys, the solution heat treatment homogenizes the casting and dissolves the δ and γ" phases, which facilitates weld repair of the casting. For these alloys a rapid cooling rate from the solution temperature is not required.

The stabilization heat treatment is employed to enhance creep-rupture properties. A temperature between the solution and aging temperature is used. The purpose of this heat treatment is to optimize the γ' size and morphology and to assist decomposition of the coarse, as-cast MC carbides into fine, grain-boundary carbides. With nickel-base alloys used for turbine airfoils, the stabilization heat treatment is often combined with the heat treatment used to bond or diffuse a coating onto the alloy substrate. In iron-nickel-base alloys a stabilization heat treatment can be used to precipitate δ phase at the grain boundaries for good notch rupture properties. Like solution heat treatment, the stabilization heat treatment is carried out in a protective atmosphere, such as argon, helium, hydrogen, or vacuum, to prevent excessive oxidation of the casting. Retorts and conventional furnaces are used to provide the stabilization heat treatment under a protective atmosphere.

Cooling rates equivalent to air cooling or faster are normally used. As the stabilization heat treatment temperature is normally several hundred degrees Fahrenheit lower than the solution temperature, coarsening of the γ' or other strengthening precipitate phases will be much slower and a rapid cooling rate is not as critical. For iron-nickel-base alloy castings, which are commonly weld repaired in the solution-treated condition, the stabilization heat treatment also serves as a stress relief.

The aging heat treatment is employed to precipitate additional γ' as very fine precipitates. This is important to achieve tensile and lower-temperature creep-rupture properties. With iron-nickel-base superalloys, γ" also precipitates during the aging heat treatment. Cooling from the aging temperature is not critical, but rates equivalent to air cooling or greater are often used. Protective atmospheres are less critical at the lower temperatures employed for aging, but they are usually used. Equipment similar to that employed for the stabilization heat treatment is used for the aging heat treatment.

Hot isostatic pressing (HIP) is a process wherein hydrostatic pressure and elevated temperature are applied concurrently. It is utilized on superalloy castings to eliminate casting porosity. HIP is usually conducted at or near the solution temperature. Use of an inert gas such as argon under high pressure as the pressure transfer medium precludes achieving a rapid cooling rate upon completion of the cycle. As a result, castings receiving a HIP cycle that require a rapid cool from the HIP temperature are given a subsequent heat treatment at atmospheric pressure so that the castings can be rapidly cooled. A pre-HIP homogenization cycle is used for some large iron-nickel alloy castings to increase the local melting temperature by homogenization of the local alloy composition.

Stress-relief heat treatments are performed following welding or other processing on the casting that increases residual stress. They are usually carried out between the stabilization and aging temperatures in a protective atmosphere.

The directionally solidified nickel-base alloys, with their higher γ' solvus temperatures, require higher stress-relief temperatures than the iron-nickel-base alloys. Stress-relief temperatures of 870 to 1080 °C (1600 to 1975 °F) are employed to stress relieve precipitation-strengthened superalloy castings.

Solid-Solution-Strengthened Iron/Nickel-,Nickel-, and Cobalt-Base Alloys. Nonprecipitation-strengthened or solid-solution-strengthened high-temperature superalloy castings are generally distinguishable from the precipitation-strengthened cast super-alloys by their relatively low content of precipitate-forming elements such as aluminum, titanium, or niobium. These iron-nickel-, nickel-, and cobalt-base high-temperature alloys are heat treated to homogenize the casting and relieve any stresses in the casting as a result of either the casting process or welding. These alloys primarily derive their strength from solid solution strengthening, with carbides being the only other phases present. With no phase reactions to control enhancement of mechanical properties by heat treatment, many of these alloys do not require any heat treatment and are often used in the as-cast condition. Representative heat treatments for several alloys are listed in Table 28.

Table 28 Typical heat treatments for solid-solution-strengthened cast superalloys

Alloy	Heat treatment
Hastelloy C	**1220 °C (2225 °F)/0.5 h/air cool**
Hastelloy S	**1050 °C (1925 °F)/1 h, air cool**
Hastelloy X	**As-cast**
Inconel 600	**As-cast**
lnconel 625	**1190 °C (2175 °F)/1 h/air cool**
FSX-414	**1150 °C (2100 °F)/4/h furnace cool + 980 °C (1800 °F)/4 h/furnace cool**
MAR-M509	**As-cast**
WI-52	**As-cast**
X-40	**As-cast**

Subsequent processing following casting, such as application of a surface coating, welding, or brazing, may impose additional heat treatment requirements. Heat treatments to bond coatings to a cast superalloy substrate are usually performed at temperatures of 980 to 1090 °C (1800 to 2000 °F). Stress relief, following joining or for other purposes, can be carried out over a broad range of temperatures. The particular temperature represents a compromise between the effectiveness of stress relief and the damage to the structure or dimensional stability of the casting. Although not truly a stress relief, some stress-relief heat treatments are conducted at temperatures sufficiently high to cause recrystallization. In a cast component local recrystallization does not normally have significant detrimental effects on the mechanical properties of the casting and is usually tolerated.

The annealing or stress-relieving heat treatments that are given to this class of nonprecipitating high-temperature alloys are normally done in a protective atmosphere to prevent oxidation or surface contamination of the casting. Heat treatment is usually conducted in a batch-type furnace; the high-temperature superalloy castings are loaded into a retort that contains a protective atmosphere such as argon or hydrogen. Vacuum can also be used. Rapid cooling rates are not usually required.

Heat Treating of Refractory Metals and Alloys

John A. Shields, Jr., Climax Specialty Metals; James M. Dahl, Carpenter Technology Corporation

Introduction

THE TERM REFRACTORY METAL can be used to describe a large number of metals. The discussion in this article is limited to the alloys of the four "classical" refractory metals: molybdenum, tungsten, niobium (columbium), and tantalum. Most commercially available alloys of these metals derive their strength from either cold working or solution hardening. Certain alloys employ dispersions of second phases to retard the recrystallization of a wrought structure, but, unlike nickel-base superalloys, no commercial refractory metal alloys use precipitation as a primary strengthening mechanism. Consequently, stress-relief and recrystallization annealing are the commonly employed heat treatments for the refractory metals.

Acknowledgements

The authors would like to thank Dr. Riad Asfahani, U.S. Steel Research Laboratory, and Dr. C. Craig Wojcic, Teledyne Wah Chang Corporation, for their assistance in preparing this article. Credit should also be extended to the authors of the niobium/tantalum section in Volume 4 of the 9th Edition of *Metals Handbook.*

General Description of Annealing Treatments

Molybdenum and tungsten alloys are normally cold worked plus stress relieved to develop their best mechanical properties such as low ductile-brittle transition temperatures. Recrystallization destroys the strengthening developed by cold working and raises the ductile-brittle transition temperature to relatively high levels. Figure 1 shows the effect of recrystallization on the ductile-brittle transition in bending for unalloyed molybdenum sheet. Stress-relief annealing reduces the level of residual stress in components and restores some of the ductility exhausted by the heavy cold reductions used in making mill products, thereby permitting further fabrication with less danger of cracking and delamination. Stress-relief annealing is mandatory after welding these materials and may also be employed after extensive machining operations. Normally, a stress-relief temperature is chosen to produce a small amount (<10%) of recrystallization in the microstructure. This treatment produces optimum ductility without significant loss of strength. It also allows annealing to be confirmed by either simple hardness testing or metallographic observation. Stress-relief annealing of material to be further worked is usually performed at lower temperatures to avoid a partially recrystallized microstructure. Working of mixed microstructures can lead to variable properties and ductility problems in the finished product. Prior processing parameters, such as the amount of reduction prior to annealing and the temperature at which deformation takes place, markedly affect the recrystallization of molybdenum and tungsten and therefore also have a strong effect on the choice of stress-relief conditions. The effect of degree of working is shown in Fig. 2 for molybdenum rolled at 1200 °C (2200 °F).

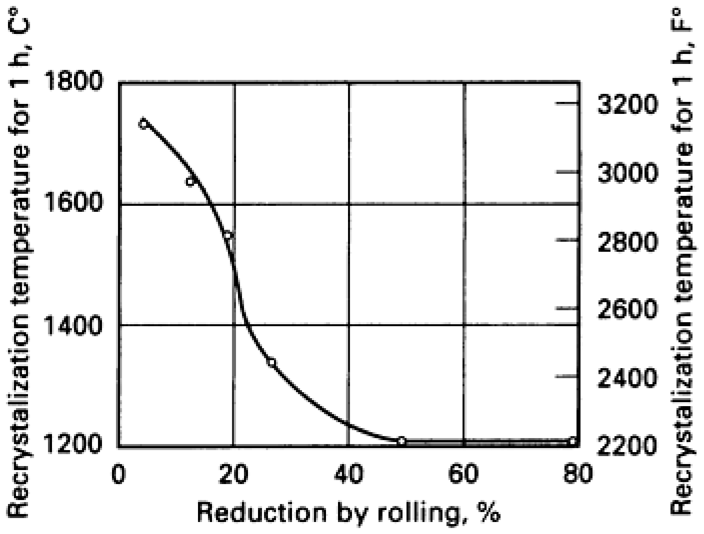

Fig. 2 Effect of degree of cold working on the minimum temperature for complete recrystallization of unalloyed arc-cast molybdenum. Courtesy of Climax Specialty Metals

A variety of proprietary stress-relief annealing practices are used by the manufacturers of molybdenum and tungsten mill products. These practices are designed to optimize fabrication properties such as the capability for hot spinning, drawing, and stamping. Typically they involve annealing to obtain a controlled amount of recrystallization in the microstructure. It is strongly recommended that users consult with a primary producer of molybdenum and tungsten to specify the appropriate product for a particular application or to optimize a specific property. Producers are also a valuable resource for advice on the heat treatment of fabricated molybdenum and tungsten products.

Table 1 lists the common commercial alloys of molybdenum and tungsten, along with typical temperature ranges for stress-relief and recrystallization annealing. It may be noted that the table does not include the lamp wire (doped tungsten) and thermocouple (W-5, 25, and 26 Re) alloys. The thermocouple alloys are not normally fabricated, other than by minimal bending and welding to form junctions, and processing parameters used in the wire and lamp manufacturing industries are highly proprietary. A more detailed discussion of annealing practice for mill products is included later in the section "Molybdenum and Tungsten Annealing Practice."

Tantalum and niobium differ greatly from molybdenum and tungsten in that these metals are ductile in the recrystallized condition. For this reason, they and their alloys are most frequently recrystallized prior to fabrication or use. In the as-rolled condition, the alloys are susceptible to cracking during forming. For less severe forming operations such as stamping, a stress-relief treatment of the as-rolled product at about 55 °C (100 °F) below the start of recrystallization suffices. However, full recrystallization annealing should precede more severe operations such as spinning, flow turning, and deep drawing. Because these alloys derive their strengthening primarily from solution hardening, the recrystallization practice depends on the alloy content of the material under consideration (including impurities such as oxygen and nitrogen), as well as the degree of cold work prior to annealing. An example of recrystallization behavior for commercial alloy C103 in sheet form is shown in Fig. 3.

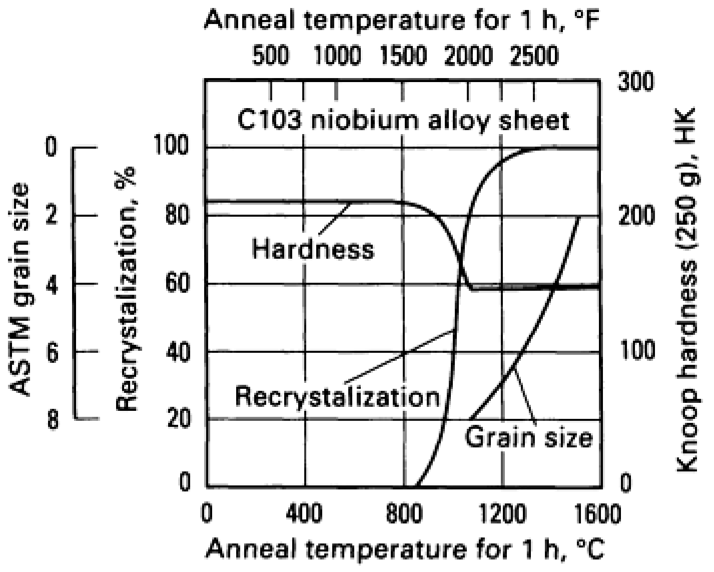

Fig. 3 Recrystallization behavior of alloy C103 for 1-h anneals in vacuum. Courtesy of Teledyne Wah Chang Corporation

Stress-relief treatments are typically used after welding to reduce residual thermal stresses and after forming operations to eliminate residual forming stresses. If components are coated after welding or forming to provide oxidation resistance, the thermal treatment involved in the coating process itself usually provides sufficient stress relief.

The common commercial alloys of tantalum and niobium are listed in Table 2, along with typical stress-relief and recrystallization annealing temperatures. The reader must bear in mind that the specific temperature required will depend on the degree of cold work and the processing history of the alloy. Annealing temperatures are not given for the niobium-hafnium-nickel-zirconium alloy in Table 2. The major application for this material is in fine, composite, superconducting wire. In this application, annealing practice during the manufacture of the composite wire has a major effect on the properties of the finished wire. Appropriate annealing practice is also a function of the other processing parameters used in wire drawing, such as drawing reductions and temperatures. For these reasons, annealing schedules for superconducting composite wire are highly proprietary and application specific. The other major application for this alloy is in aircraft rivets, where the material is purchased in the appropriate microstructural condition directly from the manufacturer. More details about annealing practice for tantalum and niobium is provided in the section "Tantalum and Niobium Annealing Practice" in this article.

Molybdenum and Tungsten Annealing Practice

Furnace atmosphere considerations are important when chosing heat-treating equipment for molybdenum and tungsten because both metals form carbides and volatile oxides. Figure 4 shows the recession of molybdenum in a variety of oxygen-containing atmospheres, while Table 3 summarizes the qualitative behavior of molybdenum and its alloys in various gas atmospheres. Tungsten would be expected to behave in a similar manner. The tendency to form brittle surface carbides and the phenomenon of volatile oxide evaporation indicate that carbon- and oxygen-containing atmospheres are to be avoided, especially for thin products such as sheet and foil. Thick-section products such as rod, bar, and plate can frequently tolerate surface recession due to oxidation and are sometimes annealed in air-atmosphere furnaces. Both hydrogen and nitrogen may be considered inert to pure molybdenum and tungsten, but internal nitriding can occur in alloys containing titanium, zirconium, and hafnium. High-purity dry hydrogen is the preferred atmosphere for annealing molybdenum and tungsten because of its compatibility with the metals and because it improves surface cleanliness by reducing surface oxides during annealing. High-quality vacuum systems may also be used to anneal these materials. Surface decarburization can occur in atmospheres containing oxygen, and this may be a problem for alloys that depend on carbide formation to stabilize the microstructure against recrystallization. Adding zirconium and titanium to the alloy can also cause the formation of undesirable oxide, carbide, and nitride phases when annealing is performed in atmospheres contaminated with oxygen, carbon, or nitrogen. If the products to be annealed are to be further machined, furnace atmosphere is less critical, and less stringent guidelines can be followed.

Table 3 Qualitative high-temperature behavior of molybdenum and its alloys in various gas atmospheres

Atmosphere	**Molybdenum behavior**	Alloy behavior
Oxygen	At higher pressures, formation of solid and liquid oxides; evaporation of volatile oxides resulting in weight losses. At low pressures, no surface oxide scales; evaporation of volatile oxides, resulting in steady states with temperature- and pressure-dependent weight losses. C-containing Mo is degassed by CO formation	**Complex oxidation behavior showing weight gains and weight losses**
		Formation of volatile oxides, possible selective evaporating; internal oxidation
Water vapor	At high pressures, oxidation and evaporation of volatile oxides and Mo-O-H compounds. At low pressures, formation of gaseous H_2 and evaporation of volatile oxides; no surface scales, steady states with temperature- and pressure-dependent weight losses	**Similar to oxygen**
Nitrogen	At high temperatures, pressure-temperature-concentration equilibriums with low N concentrations even at high pressures. At low temperatures, no reaction	**Pressure-temperature-concentration equilibriums, internal nitriding**
Ammonia	At high temperatures, NH_3 is dissociated into H_2 and N_2 with solid solution formation; at low temperatures, nitride formation	**At high temperatures, NH_3 dissociation, formation of solid solutions, and/or internal nitriding. At lower temperatures, external and/or internal nitriding**
Carbon monoxide	Solution of C and O; carbide formation; oxide evaporation	**Solution of C and O; external and/or internal carbide and oxide formation, oxide evaporation**
Hydrogen	Formation of solid solution, low H concentration even at high H_2 pressures; at high H_2O/H_2 ratios, possible oxygen degassing; at high H_2/CH_4 ratio, possible carbon degassing	**Formation of solid solution and/or internal hydride formation**
Hydrocarbons	Carbon solution and carbide formation with H_2 desorption	**Carbon solution and external and/or internal carbide formation**
Inert gas	Reduction of metal evaporation; in case of oxygen-containing impurities, formation of volatile oxides resulting in additional metal losses	**Reduction of evaporation of base or alloying metals; in case of oxygen-containing impurities, oxidation processes**
Vacuum	**Degassing of H and N via H_2 and N_2 desorption, degassing of C and O via CO formation, degassing of O via oxide evaporation; at high residual pressures, contamination possible**	**Degassing processes, contamination**

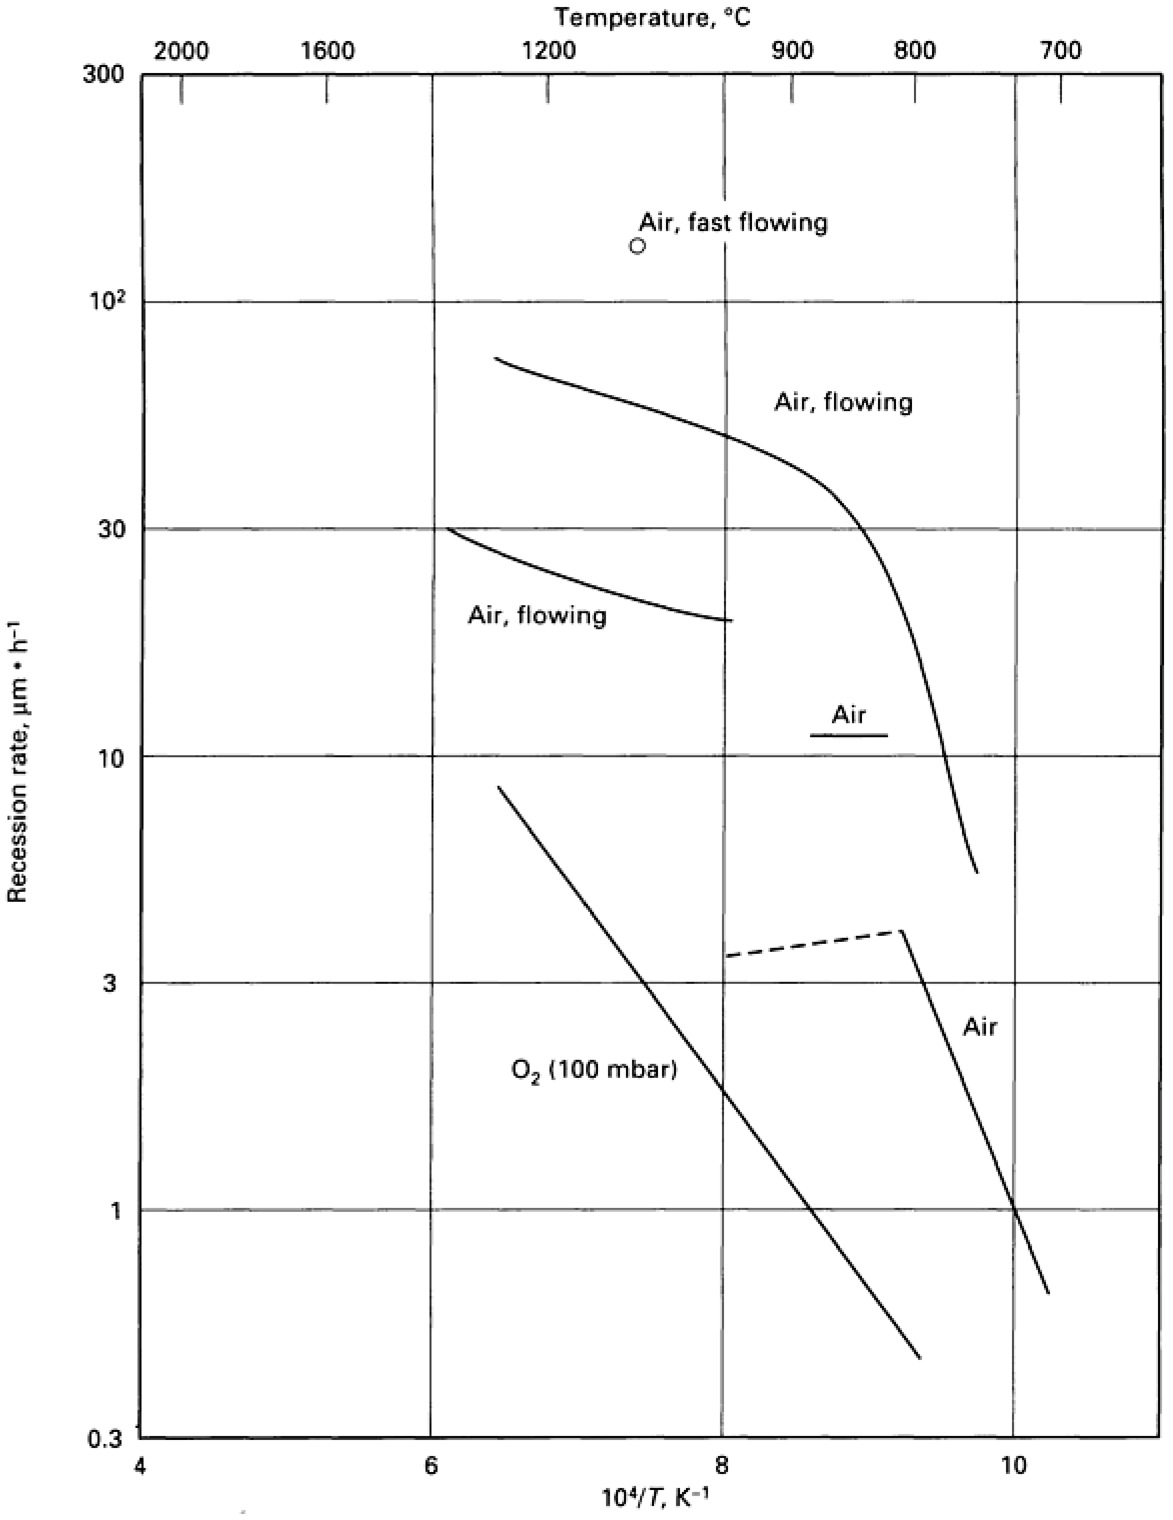

Fig. 4 Oxidation of molybdenum in pure oxygen and air. T, temperature. Source: Ref 1

Cleaning of molybdenum and tungsten is desirable to remove compounds that could cause carbon contamination during heat treatment. If components are heavily oxidized as a result of hot forming in air, it is wise to remove the oxide chemically prior to annealing in order to maintain furnace cleanliness. A variety of cleaning agents may be used to remove oils and hydrocarbons. Vapor degreasing and hand or automatic washing with detergent solutions both work well. For chemical cleaning, molten caustic (1.5 to 3% sodium nitrite in sodium hydroxide at 425 °C, or 800 °F) followed by hot water rinsing effectively removes heavy surface oxides.

Recrystallization behavior of molybdenum is shown in Fig. 5. The data for this figure were obtained on 1.6 mm ($\frac{1}{16}$ in.) vacuum arc-cast sheet, but are also useful for estimating the behavior of other gages. Thinner sections, having greater degrees of cold work, will have curves shifted to lower temperatures. Thicker sections will recrystallize at higher temperatures.

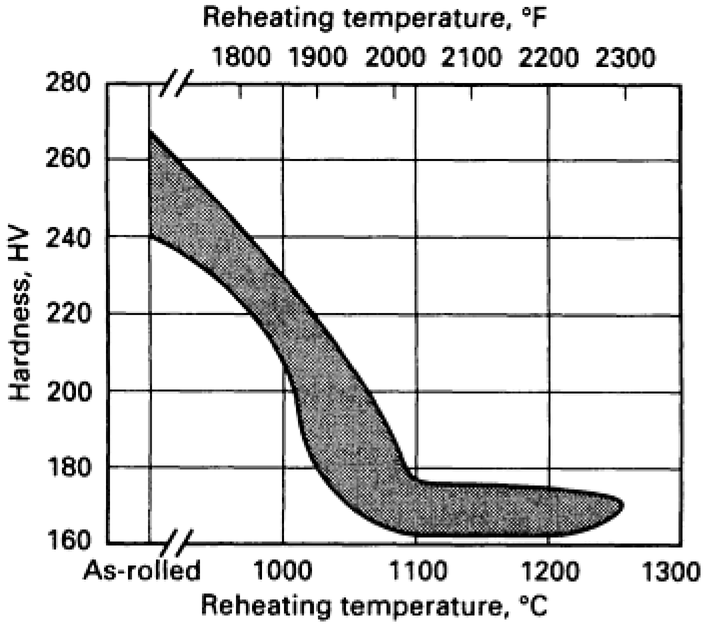

Fig. 5 Recrystallization behavior of 1.6 mm ($\frac{1}{16}$ in.) vacuum arc-cast molybdenum sheet, as reflected by room-temperature hardness after 1-h anneals at the indicated temperature. Courtesy of Climax Specialty Metals

Because molybdenum and tungsten suffer increases in their ductile-brittle transition temperature in the recrystallized condition, mill products are normally supplied in the stress-relieved condition. The exceptions to this rule are molybdenum and tungsten forging billets, which by definition require further working. For this reason, powder-metallurgy molybdenum and tungsten forging billets are normally supplied in the pressed and sintered condition and do not require thermal treatment prior to forging. Vacuum arc-cast molybdenum and tungsten forging billets are typically produced from extruded ingots and are supplied in the fully recrystallized condition. Because the ductile-brittle transition temperature of recrystallized molybdenum and tungsten is very sensitive to grain size, a recrystallization temperature is chosen that will produce the smallest grain size possible in the recrystallized product.

Figure 6 summarizes a range of data on the recrystallization behavior of arc-cast TZM molybdenum alloy (UNS R03630). This figure may be used to estimate the time required for recrystallization at a given temperature, or vice versa. Again, the figure shows clearly the effect of gage, with the thinner gages recrystallizing at smaller values of the exposure parameter than thicker gages. Figure 7 is a composite of recrystallization information on a variety of arc-cast TZM alloy mill products. It can be seen that the degree of cold work most strongly affects the temperature at which recrystallization begins and has less effect on the temperature for complete recrystallization.

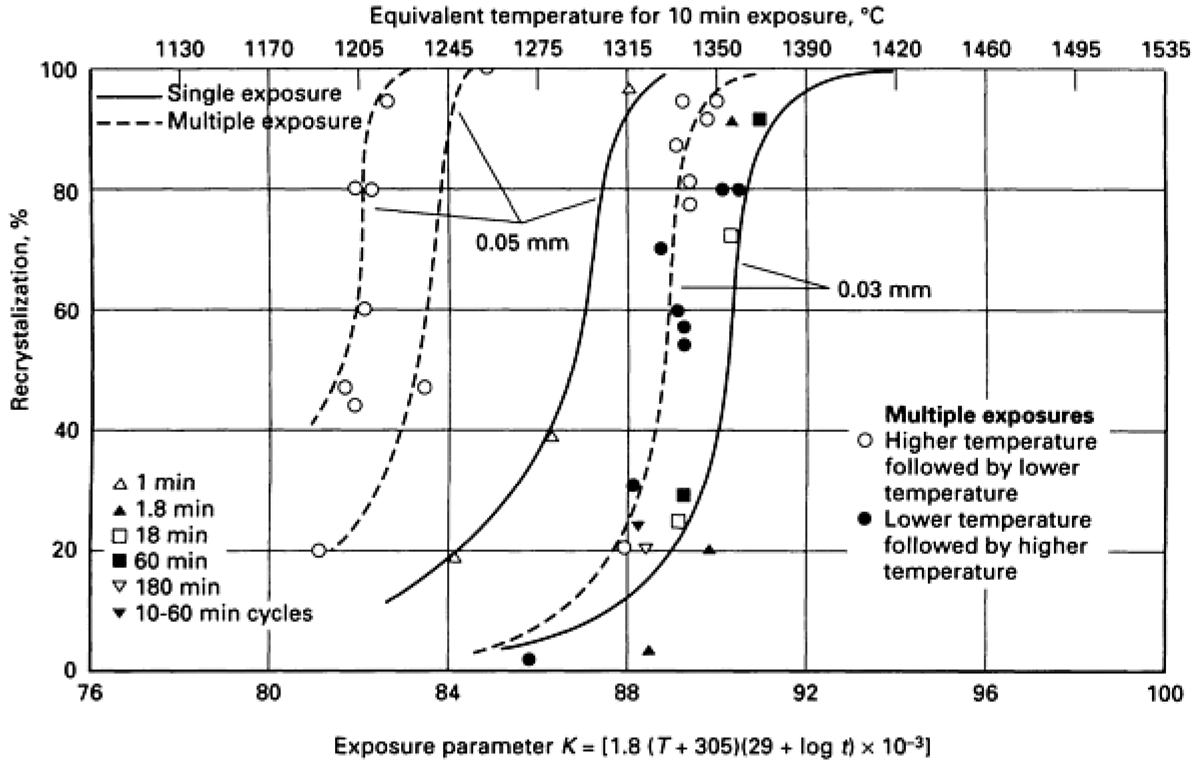

Fig. 6 Recrystallization behavior of arc-cast TZM alloy, as defined by a thermal exposure parameter (*K*) with temperature (*T*) in degrees Celsius and time (*t*) in minutes. Source: Ref 2

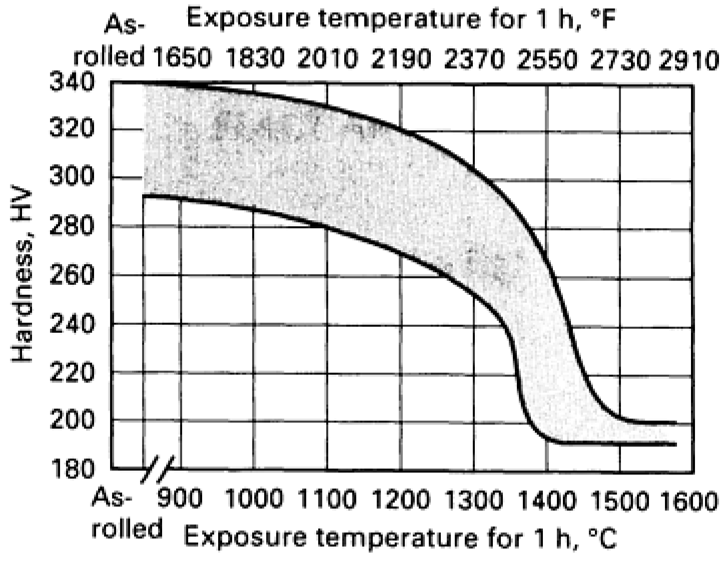

Fig. 7 Scatter band of room-temperature hardness versus 1-h exposure temperature for rolled arc-cast TZM bar and sheet products. Source: Ref 3

Stress-relief annealing of tungsten and molybdenum may be accomplished by annealing slightly below the temperature required to initiate recrystallization. The curves of Fig. 4, 5, and 6 may be used to estimate the temperature required for stress relief, or the recommendations of Table 1 may be followed. Pilot annealing on material from the same lot, using the table and figures as guidelines, can also be employed to custom-tailor the annealing practice for a particular application. As noted previously, normal practice is to select a final stress-relief temperature that results in a small amount (<10%) of recrystallization in the microstructure.

Tantalum and Niobium Annealing Practice

Table 2 lists general recommendations for the annealing temperatures of tantalum and niobium materials. The trend toward bonding tantalum and niobium to other metals presents special problems that must be carefully reviewed from a metallurgical standpoint. The recommendations of Table 2 probably do not apply to most clad materials.

It is strongly suggested that users contact the supplier of the primary fabricated metal to review plans and procedures prior to any thermal treatment of tantalum, niobium, or their alloys. Numerous expensive failures have resulted from attempts to perform thermal treatment in air, in atmospheres with inadequate inert-gas protection, or in inadequate vacuum systems.

Furnace atmosphere control during the heat treatment of tantalum and niobium is even more important than it is for tungsten and molybdenum. These metals absorb oxygen, nitrogen, and hydrogen from the atmosphere as temperatures increase above 650 °C (1200 °F). The surface oxidation of both metals occurs in air above 300 °C (570 °F), and the oxidation rate increases with increasing temperature. Carbon can also be absorbed if the carbon potential of the furnace atmosphere is sufficient. Hydrogen embrittlement may occur in hydrogen-containing atmospheres. Hydrogen absorption in tantalum and niobium takes place at low temperatures but desorption occurs as temperatures increase from 200 to 1000 °C (400 to 1830 °F). Although this provides a method of hydrogen removal, cooling in the presence of hydrogen should be avoided.

The impurities picked up from furnace atmospheres form brittle surface layers that are detrimental to further forming and machining operations and to service performance. The heat treatment of materials with brittle surface layers will result in the diffusion of the embrittling species into the bulk of the material. Because the metals are readily embrittled by the addition of even a few hundred parts per million of oxygen, nitrogen, carbon, or hydrogen, this diffusion can render the entire cross section brittle. To prevent the pickup and diffusion of these interstitial elements during heat treating, appropriate surface-cleaning procedures, furnace maintenance, and operational practices are essential.

Furnace Selection. Because these alloys are easily contaminated during annealing, special care must be exercised in furnace selection, cleanliness of work, and annealing practice. Cold-wall radiant-heated furnaces with refractory metal heating elements, primary heat shields, permanent hearth materials, and support fixtures are normally used when heat treating niobium and tantalum. These furnaces operate at vacuums of 0.01 Pa (10^{-4} torr) or greater and have low leak rates. Hot-wall argon atmosphere furnaces have also been used to anneal tantalum and niobium, but adsorbed gases and metals on hot furnace walls are likely to cause contamination. Argon must be free of hydrogen and have a dew point below -50 °C (-60 °F).

Leak rate control is the key to the successful heat treating of tantalum and niobium alloys, especially with products having high surface-to-volume ratios, such as low-gage wire, tube, and strip. Leak rate must be measured in a stabilized system, that is, one that has pumped for a period of time and is no longer outgassing. It is defined as the pressure rise (typically in torr) per second, per liter of chamber volume. The example below illustrates the measurement of leak rate.

Assume that a 1200 l (42.4 ft^3) vacuum furnace chamber is isolated by closing the high-vacuum valve. The pressure rise is observed, and an increment of rise is timed by a stopwatch. Assuming the chamber pressure rises 0.25 Pa (2×10^{-3} torr) in 5 min, the leak rate would be calculated as:

$$\frac{\text{Pressure change . Chamber volume}}{\text{Time}} = \frac{2x10^{-3}.1200}{300} = 0.8\ x\ 10^{-2} torr.l/s$$

where pressure change is measured in torr, chamber volume in liters (l), and time in seconds (s). This rate is acceptable because it is below the suggested limit of 10^{-2} torr · l/s. The full calculation need not be carried out for every measurement because for a particular furnace the leak rate criterion implies a particular pressure rise rate. In the above example, the pressure rise would have to be less than $\frac{1}{3}$ Pa (2.5 × 10^{-3} torr) in 5 min for the furnace to satisfy the leak rate criterion.

Furnace Cleanliness. Furnaces must be clean and usually must not be used for other operations or other metals unless a given practice has been found to be satisfactory. Furnaces previously used to perform brazing operations should not be used. Good practice dictates that furnaces be heated to a temperature 100 °C (180 °F) above the annealing temperature in the empty condition to remove adsorbed gases. As further insurance, tantalum foil is frequently used as an outer wrapping on parts to react with impurities in the furnace.

If furnaces are refurbished for use with tantalum and niobium after being used with other materials, care must be taken to clean and decontaminate thoroughly all furnace components. Vacuum furnaces employing argon quenching and gas recycling will suffer deposition of volatile elements (braze alloys, chromium in nickel-base and stainless alloys) in the argon heat exchanger. If the heat exchanger is not thoroughly cleaned as part of the furnace refurbishment, argon quick cooling with tantalum and niobium loads can redeposit these elements on the refractory metal surfaces.

Furnace qualification is often a customer requirement and usually includes a limit on the amount of allowable contamination as measured by increased hardness or interstitial content. If there is any doubt regarding furnace quality, it would be prudent to overlap components in tantalum or niobium foil.

Cleaning of tantalum and niobium is a critical step in preparation for heat treatment. All surface contamination must be removed by machining or grinding and pickling before annealing because of the embrittlement mentioned previously. Cleaning and degreasing present no special problems. Conventional methods and materials may be used, although hot caustics must be avoided. First, thorough degreasing is carried out using a detergent or solvent. Degreasing is followed by chemical etching, typically with a mixture of 60% HNO_3, 20% HF, 20% H_2SO_4 (vol %); hot and cold water rinses in distilled water; and spot-free drying. The etching solution may be either strengthened by HF or weakened by water to achieve the amount of stock removal necessary to ensure the cleanliness of the metal surface. One company eliminates H_2SO_4 because some evidence indicates that it can contribute to weld embrittlement. Nitric acid should always be present, however, because it prevents hydrogen pickup during pickling. Further, elevated-temperature forgings will have an oxygen-contaminated outer layer, and this must be removed from all surfaces by machining or grinding before acid pickling.

Recrystallization annealing is the most common thermal treatment applied to tantalum and niobium alloys. The recrystallization temperature is so highly dependent on purity, amount of cold work, and prior history that current practice is to anneal pilot samples to ensure that the correct temperatures are used. Time at temperature is typically 1 h.

Table 2 can be used as a guide for choosing pilot temperatures. Materials given heavy fabrication reductions will recrystallize to finer grain sizes at lower temperatures than those given lighter fabrication reductions. The recrystallization annealing temperature is also somewhat dependent on interstitial purity. For example, pure tantalum containing 200 ppm O requires a higher recrystallization annealing temperature than does pure tantalum containing less than 50 ppm O.

A typical annealing sequence is:

- Visually verify material cleanliness
- Load, using tantalum, tantalum alloy, or molybdenum fixtures for support, or tantalum foil for protection, as required
- Pump down
- Check leak rate
- Turn on power to temperature
- Hold at temperature for required time
- Turn power off

- When temperature drops below 1000 °C (1830 °F), backfill to 2000 Pa (15 mm Hg) with industrial high-purity (99.995% min) argon or helium
- Before removing load from furnace, allow to cool to below 200 °C (390 °F), which can require from 3 to 5 h depending on furnace size and mass of load

This sequence is not intended to be a detailed procedure for annealing these materials but rather to create an awareness of the difficulties and risks of heat treating these materials to avoid the repetition of costly past errors. The major risk is loss of vacuum at a temperature that results in the extremely costly destruction by oxidation, not only of parts being heat treated, but also of the furnace shielding and heating elements.

Principles of Heat Treating of Nonferrous Alloys

Charlie R. Brooks, University of Tennessee

Introduction

THE PRINCIPLES which govern heat treatment of metals and alloys are applicable, of course, to both ferrous and nonferrous alloys. However, in practice there are sufficient differences to make it convenient to emphasize as separate topics the peculiarities of the alloys of each class in their response to heat treatment. For example, in nonferrous alloys, eutectoid transformations, which play such a prominent role in steels, are seldom encountered, so that the principles associated with time-temperature-transformation diagrams and with martensite formation are not emphasized in this article. On the other hand, the principles associated with chemical homogenization of cast structures are applicable to many alloys in both classes.

Examination of the heat treatment used for nonferrous alloys reveals that a wide variety of processes are employed. However, because the process of diffusion underlies nearly all heat treatments, the concepts of diffusion are summarized first in this article. Annealing after cold working is a very important heat treatment for nonferrous alloys, and this topic is discussed next. Then the subject of homogenization annealing is reviewed, because it is an important heat treatment for as-cast structures. The process of precipitation, and the hardening that accompanies it, are described next, because these phenomena are especially important in aluminum-base alloys (and also in some magnesium, copper and nickel-base alloys). Then, to illustrate the formation of structures in which two phases are present in comparable quantities (for example, titanium-base alloys, some copper brasses, and so on), the heat treatments of a specific type of Cu-Zn alloy are examined. Finally, references are listed which provide additional information on the principles of heat treatment of nonferrous alloys.

Diffusion in Metals and Alloys

In heat treatment of metals and alloys, the rate of structural changes is usually controlled by the rate at which the atoms in the lattice change position. Thus, when cold worked copper is annealed and softens, or an aluminum-base alloy is aged, we are interested in how the atoms move relative to each other so as to bring about the observed changes in properties. The movement of the atoms involved here is called diffusion, and it is this process of diffusion which is examined in this section.

Diffusion in Pure Metals (Self-Diffusion). Atoms in a lattice at finite temperatures are not static, but are vibrating in three dimensions around the normal atom position, usually the lattice site. Thus, consideration arises as to whether these atoms, by some mechanism, can exchange positions with each other and thereby move through the lattice. Such movement of the atoms of a pure metal is termed self-diffusion, and it is usually detected by experiments in which a thin layer of a radioactive atom is placed on the surface (for example, by plating) of the same metal which is not radioactive and then the sample is given an annealing treatment at sufficient temperature and for sufficient time to allow diffusion. Because the difference between the radioactive and nonradioactive atoms is in the nuclear structure, and not in the valence electrons which are related to bonding, it is assumed that the radioactive atoms move through the lattice by the same mechanism and at the same rate as do the nonradioactive atoms. Thus, the movement of the radioactive atoms, which can be followed by a suitable radioactivity detector, reflects the type of movement the atoms in the metal undergo.

Such an experiment is illustrated schematically in Fig. 1. The radioactive layer is depicted as only two atoms thick, whereas it will really be much thicker (for example, 1 mm). The sequence of time from 0 to t_3 shows increasing amounts of radioactive atoms (closed circles) moving into the lattice of the nonradioactive atoms (open circles), and simultaneously the lattice sites of the radioactive atoms are occupied by the nonradioactive atoms. The amount of radioactivity is measured as a function of depth into the sample from the surface, giving the profiles shown at the bottom of the figure. (Note that Fig. 1 does not show the intensity in the radioactive layer; it will decrease with time due to radioactive decay. This decay will also alter the intensity-depth curves, but this correction is not shown in the schematic curves in Fig. 1.)

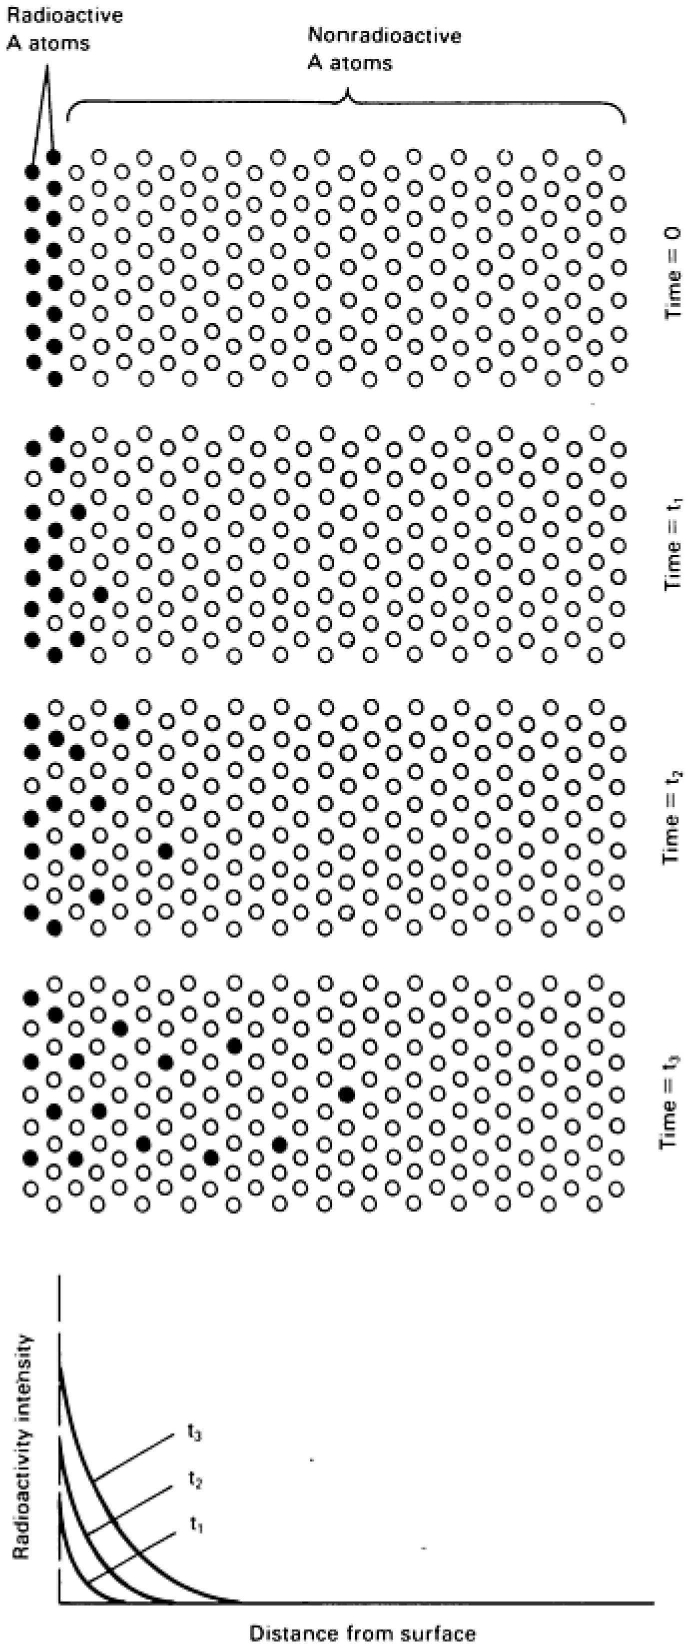

Fig. 1 Schematic diagram showing self-diffusion in a pure metal (radioactive atoms represented by solid circles)

Vacancies. The movement of atoms in the lattice, as depicted in Fig. 1, can be conceived to occur by several mechanisms. For example, at any instant in time, it is possible that the nearest two neighboring atoms have vibrated in

directions so that space is left around the two atoms, allowing them to exchange positions simultaneously. Such an event is depicted in Fig. 2(a). It is clear that the two atoms which exchange positions must move, to some extent, the neighboring atoms in order to pass each other during the exchange process. It may also be possible for four atoms to vibrate at some instant so that they move cooperatively in a ring, allowing all four to move simultaneously to new neighboring positions, as depicted in Fig. 2(b).

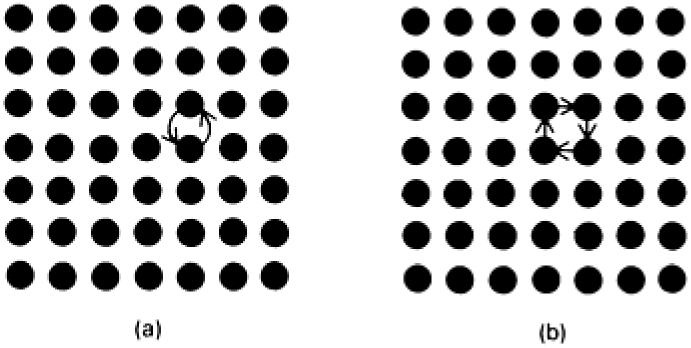

Fig. 2 Schematic representation of two possible diffusion mechanisms. (a) Two atoms move simultaneously to exchange positions. (b) Four atoms move cooperatively to rotate simultaneously to move to new positions.

Although mechanisms such as those just suggested probably occur in some alloys, in most metals and alloys diffusion occurs by vacancy movement. An unoccupied normal atom position in the crystal structure (usually a lattice site) is a vacancy. The presence of vacancies in a lattice at equilibrium is a consequence of a balance between the energy required to form the vacancies ΔH and the entropy ΔS created by their presence. Thus, there is an equilibrium concentration which minimizes the free energy change ($\Delta G = \Delta H - T\Delta S$).

If a vacancy exists in a lattice, then it requires much less energy for an atom to change positions than in the mechanisms depicted in Fig. 2. An atom has only to move into the vacancy, with much less energy. Such movement is shown in Fig. 3. It is to be noted that the diffusion occurs by rather random movement of the vacancies throughout the lattice.

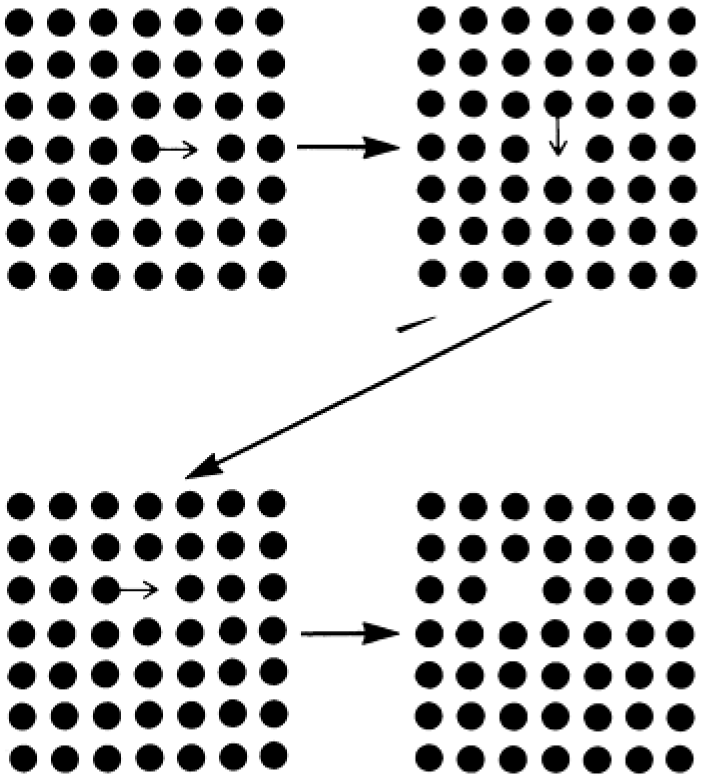

Fig. 3 Schematic depiction of diffusion by vacancy movement. The vacancy moves to the new positions with time as shown by the small arrows. The large arrows show the changes with time.

Diffusion in Alloys (Chemical Diffusion). When two metals (or alloys) are placed in contact, atoms will begin to migrate across the contacting interface. Such diffusion of unlike species is called chemical diffusion, and is illustrated schematically in Fig. 4. (For the process to occur as shown in Fig. 4, the metals have to be soluble in each other; otherwise, when sufficient amounts of one metal diffuse into the other to reach a concentration corresponding to the solubility limit, precipitation of a second phase occurs.) The chemical diffusion depicted in Fig. 4 actually occurs by vacancy diffusion.

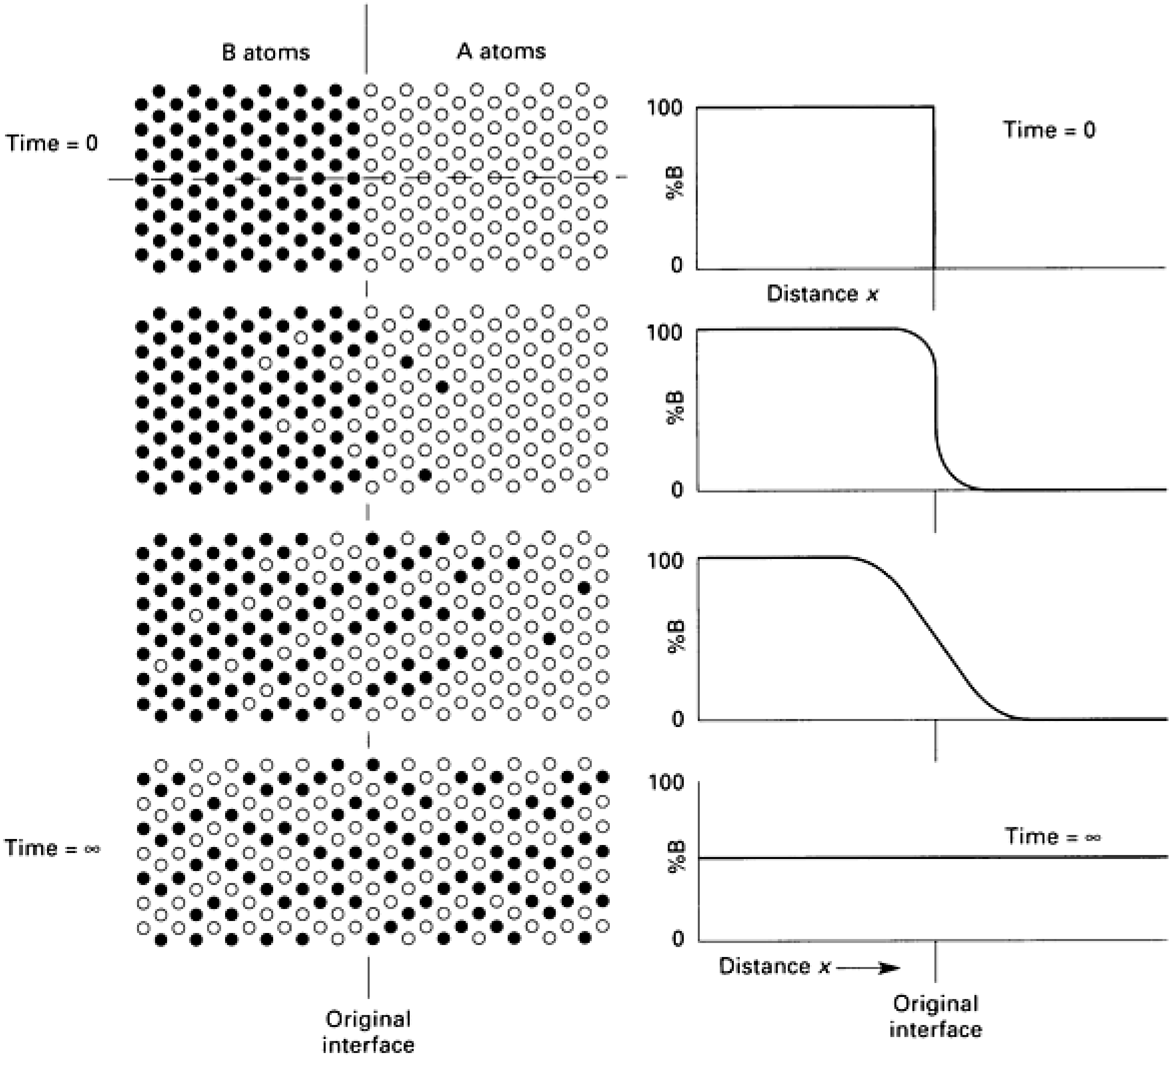

Fig. 4 Schematic illustration of chemical diffusion involving two different metals. The diffusion couple is made up of pure B (solid circles) and pure A (open circles). As time progresses, mixing on the two sides occurs. At infinite time, complete mixing has been achieved, with the chemical composition being identical on both sides.

Fick's Laws of Diffusion. The mathematical relation that connects the concentration of the diffusing species with distance is Fick's law, a phenomenological equation which fits well most diffusion data. Fick's first law states that the diffusion flux, J (in one-dimensional diffusion), is given by:

$$J = -D(dC/dx) \qquad \textbf{(Eq 1)}$$

where C is concentration and x is distance. D is a constant at a given temperature, but may be concentration-dependent; it is called the diffusivity or diffusion coefficient. Figure 5 illustrates the relation between these terms and the concentration profile associated with chemical diffusion, such as illustrated in Fig. 4. Figure 6 shows data typical of those obtained by machining thin layers from a diffusion couple and analyzing each for the amount of the metals present. The diffusion flux (if concentration is put in proper units) is defined as thenumber of atoms of the diffusing species which pass through a plane of unit area, which is normal to the diffusion direction, per unit time. Thus, the flux may be given in terms of number of atoms per square centimeter per second.

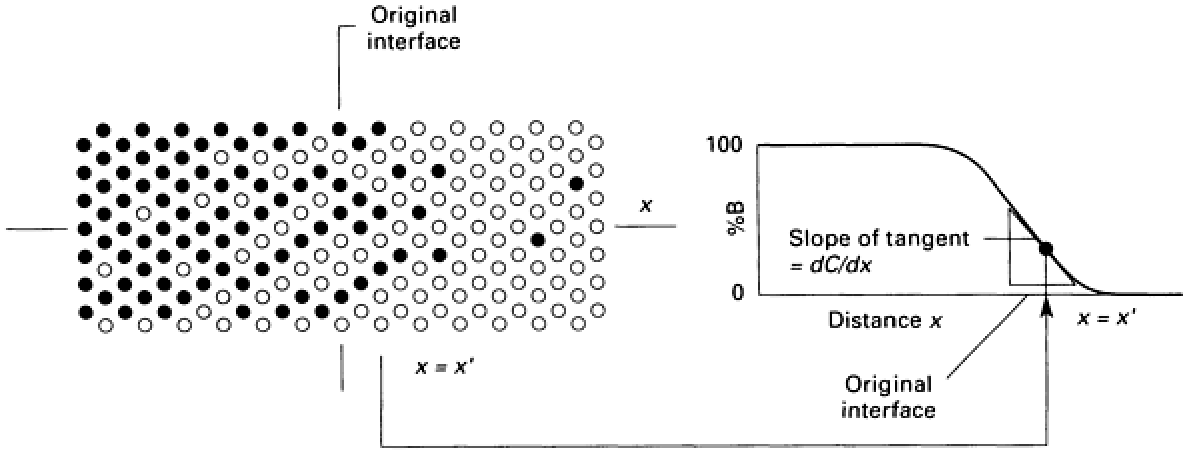

Fig. 5 Illustration of the meaning of the terms in Fick's first law of diffusion. Flux of atoms across the plane at $x = x'$ is the number of atoms crossing a plane 1 cm square per unit time (s) and is proportional to the gradient dC/dx at that location ($x = x'$): $J = -D(dC/dx)$. The proportionality constant is the diffusivity or diffusion coefficient. The negative sign is required to make the flux positive to be physically realistic, as the gradient dC/dx is negative.

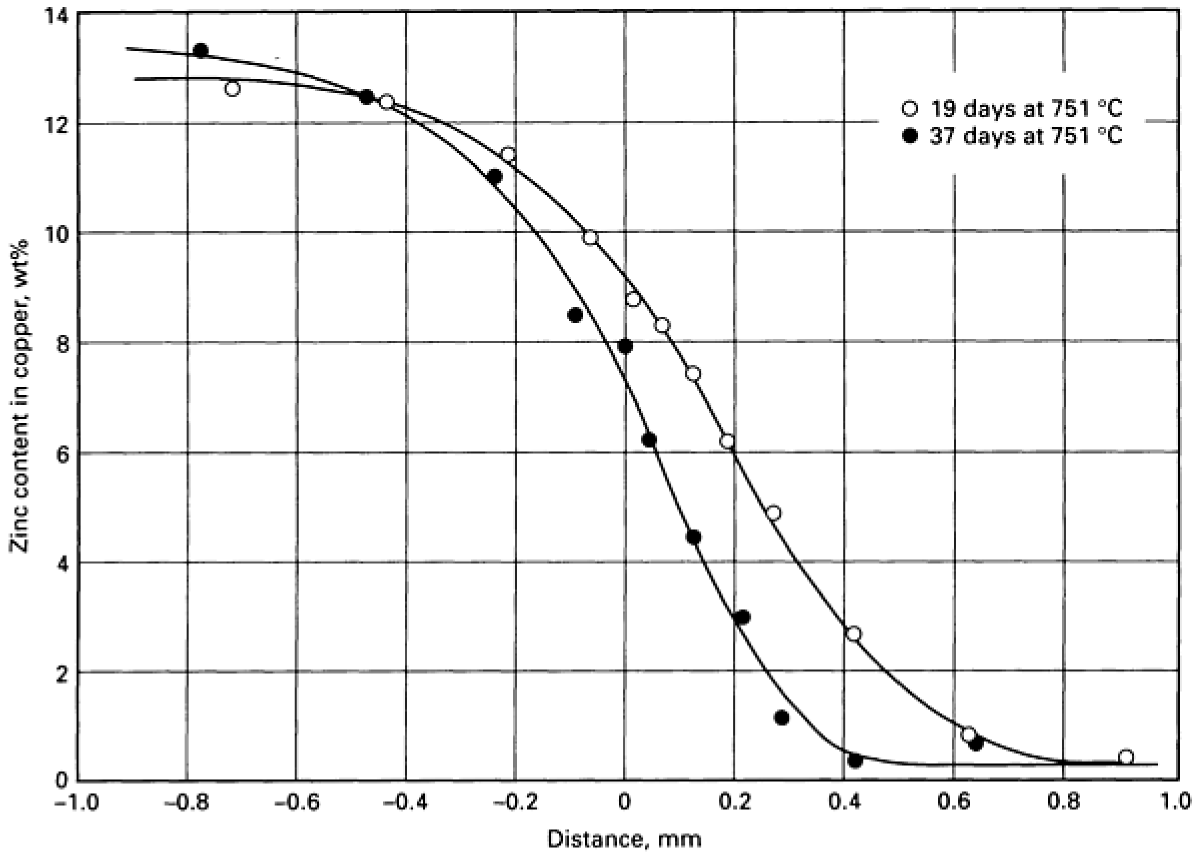

Fig. 6 Concentration profile data typical of metals obtained from a diffusion couple, which in this case was copper-zinc. Each point represents the chemical analysis of a thin layer machined from the sample. Adapted from Ref 1

The effect of time, *t*, on the flux is incorporated in Fick's second law (again, for one-dimensional diffusion):

$$dC/dt = D\frac{d}{dx}(dC/dx) = D\frac{d^2C}{dx^2} \qquad \textbf{(Eq 2)}$$

If the diffusion couple consists of two pure metals A and B that are completely soluble in each other, the solution to this equation is:

$$C_A = \frac{1}{2}\ [1 - f\ (x/2\sqrt{Dt})] \qquad \textbf{(Eq 3)}$$

where f is the Gauss error function and C_A is the concentration of A at distance *x* from the original interface. (Similar expressions are obtained for different starting conditions--for example, an alloy coupled against a pure metal, and so on. See Ref 2.) To extract *D*, then, for a given diffusion time *t* at a given distance *x*, the value of C_A is obtained (for example, read from Fig. 6). This allows a value of $f\ (x/2\sqrt{Dt})$ to be obtained. Then, error function tables are used to determine the argument of $f\ (x/2\sqrt{Dt})$--that is, to determine a value for $(x/2\sqrt{Dt})$. Then *D* is obtained.

Such a procedure should yield the same value of *D* no matter what value of *x* is chosen. However, it is found that *D* will usually vary, meaning that it is a function of composition. In this case, the equation to use is:

$$dC/dt = \frac{d}{dx}(DdC/dx) \qquad \textbf{(Eq 4)}$$

The solution is more complicated, but allows determination of the diffusion coefficient as a function of composition (see Ref 2).

An important practical relation evolves from the solution to Fick's second law--namely, that the time-distance relation for a given concentration *C* is $x^2 \cong Dt$. This means, for example, that during a homogenization treatment designed to remove the effects of dendritic segregation (coring), the time is proportional to x^2, where *x* is approximately the dendritic arm spacing. This expression is a conservative approximation, and more exact solutions are available in the text by Shewmon (Ref 2).

Temperature Dependence of the Rate of Diffusion. The dependency of the rate of diffusion on temperature is found to be exponential, which is not surprising, because many rate reactions obey such a dependency. Thus, *D* is given by:

$$D = D_0\ e^{-B/T} \qquad \textbf{(Eq 5)}$$

where D_0 and *B* are constants, and *T* is absolute temperature. Theoretical treatments show that this should be written as:

$$D = D_0 e^{-Q/RT} \qquad \textbf{(Eq 6)}$$

where *R* is the ideal gas constant and *Q* is the activation energy for the diffusion process. *Q* reflects the energy required to move an atom over a barrier from one lattice site to another; the barrier is associated with the requirement that the atom must vibrate with sufficient amplitude to break the nearest neighboring bonds in order to move to the new locations.

The values of D_0 and Q shown in Table 1 typify those found in metals. The equation above for the temperature dependency of D predicts that log D plotted versus $1/T$ should be a straight line, and Fig. 7 shows some typical linear results for metals and alloys.

Table 1 Values of the diffusion constant (D_0) and the activation energy (Q) for diffusion in various substitutional and interstitial solid solutions

Solute	**Solvent (host structure)**	**D_0, cm^2/s**	**Q, kcal/mole**
Substitutional diffusion			
Copper	Copper	0.78	50.50
Copper	Tin	0.11	45.00
Copper	Nickel	1.92	68.00
Nickel	Copper	1.1	53.80
Copper	Aluminum	0.647	32.27
Zinc	Copper	0.73	47.50
Lead	Lead	0.887	25.50
Titanium	Titanium	0.000358	31.20
Aluminum (4%)	Copper	0.0455	39.50
Zinc (24-29%)	Copper	0.095	35.00
Interstitial diffusion			
Hydrogen	Copper	10^{-2}	10.00
Oxygen	Copper	10^{-3}	46.00
Carbon	Titanium	0.00302	20.00
Oxygen	Titanium	1	40.00
Hydrogen	Tantalum	. . .	6.00

Carbon	Tantalum	0.0061	38.52
Nitrogen	Tantalum	0.0056	37.84
Oxygen	Tantalum	0.0044	25.45

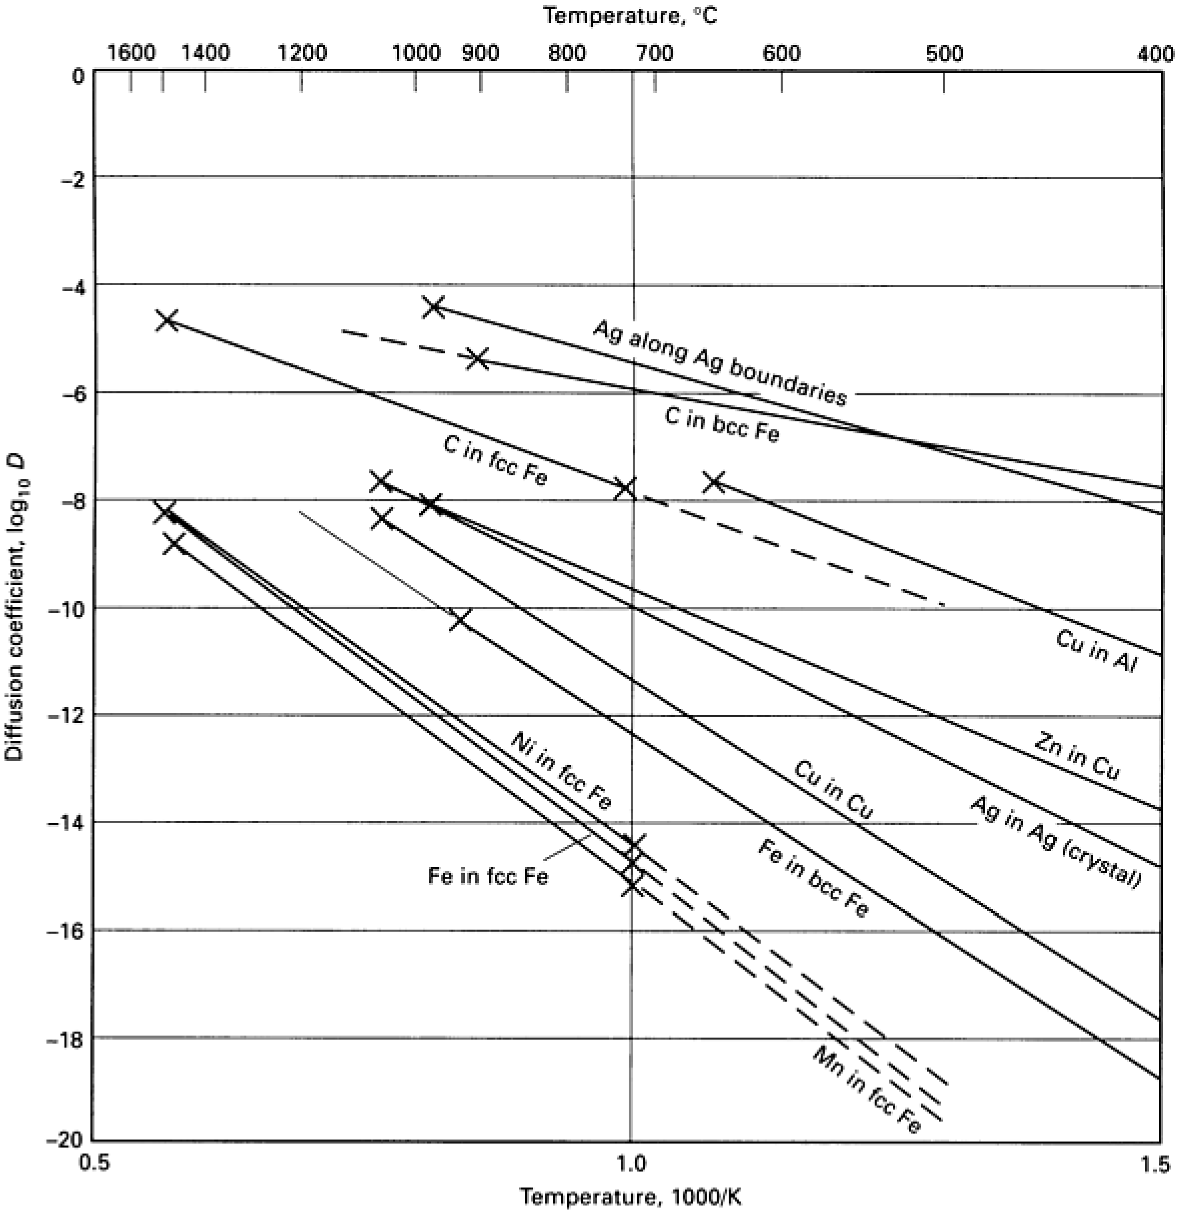

Fig. 7 Plots of diffusion coefficients and temperature (log *D* versus 1/*T*) for several metals. The straight lines are prominent and commonly found. Source: Ref 3

The exponential temperature dependence is important in heat treating. It shows that the rate of change in processes which are diffusion-controlled will increase greatly with an increase in temperature. Thus, an increase in temperature of 10 K will approximately double the rate of the process.

Intrinsic Diffusion Coefficients. If the original interface of the diffusion couple is identifiable, then experiments show that the location where half of the diffusing species will have moved from one side to the other does not coincide

with the original interface. This is sometimes referred to as the *Kirkendall effect*, and is taken as strong experimental evidence of the vacancy mechanism of diffusion in metals. Darken showed that the relation between the measured diffusion coefficient (as described above) and the intrinsic diffusion diffusivities of the individual atom species (for a binary system of atoms A and B) is:

$$D = C_A D_A + C_B D_B \qquad \textbf{(Eq 7)}$$

Here C_A and C_B are the mole fractions of A and B, respectively, and D_A and D_B are the intrinsic diffusivities of A and B, respectively. D_A and D_B are concentration-dependent.

Interstitial Diffusion. If the solute atom is sufficiently small, it will locate in an interstice between the larger solvent atoms, forming an interstitial solid solution. Diffusion of interstitial atoms occurs, not by a vacancy mechanism, but by the atoms jumping from one interstitial site to another. (Fick's laws still apply.) As the interstitial solute atom increases in size, the activation energy increases (Table 1), showing that it becomes more difficult for the atom to move between the solute solvent atoms to a neighboring interstitial site. In general, the activation energy for interstitial diffusion is less than that for substitutional diffusion.

Grain-Boundary Diffusion. Experimental studies have shown that diffusion along grain boundaries, along the core of dislocations and on free surfaces is considerably more rapid than diffusion through the interior of a crystal. Of particular interest here is grain-boundary diffusion, which influences precipitation and phase changes at the boundary. The data in Fig. 7 for self-diffusion in silver show that the grain-boundary diffusivity is several orders of magnitude greater than bulk diffusion. Also, as temperature decreases, bulk diffusion becomes slower and grain-boundary diffusion becomes more important.

Annealing of Cold Worked Metals

Dislocations. Plastic deformation in metals and alloys occurs primarily by relative movement or slip of blocks of material on specific crystallographic planes (slip planes) and in certain directions (slip directions). (Plastic deformation in metals can also occur by twinning. However, in the brief treatment here, this mechanism will not be discussed.) This occurs not by movement of regions of the crystal as a whole, but by movement of successive dislocations. A dislocation is a lattice effect (either edge or screw) which is present in even well-annealed metals as a consequence of prior processing. Dislocations play a central role in plastic deformation because less energy is required to produce slip by movement of the dislocations than by movement of entire regions of a crystal past each other. This process is illustrated in Fig. 8 for an edge dislocation. Obviously, millions of dislocations must repeat this process in order to generate visually obvious shape changes. This is possible, however, because the dislocations, which are present in the metal prior to plastic deformation, create other dislocations by a multiplication mechanism during plastic deformation.

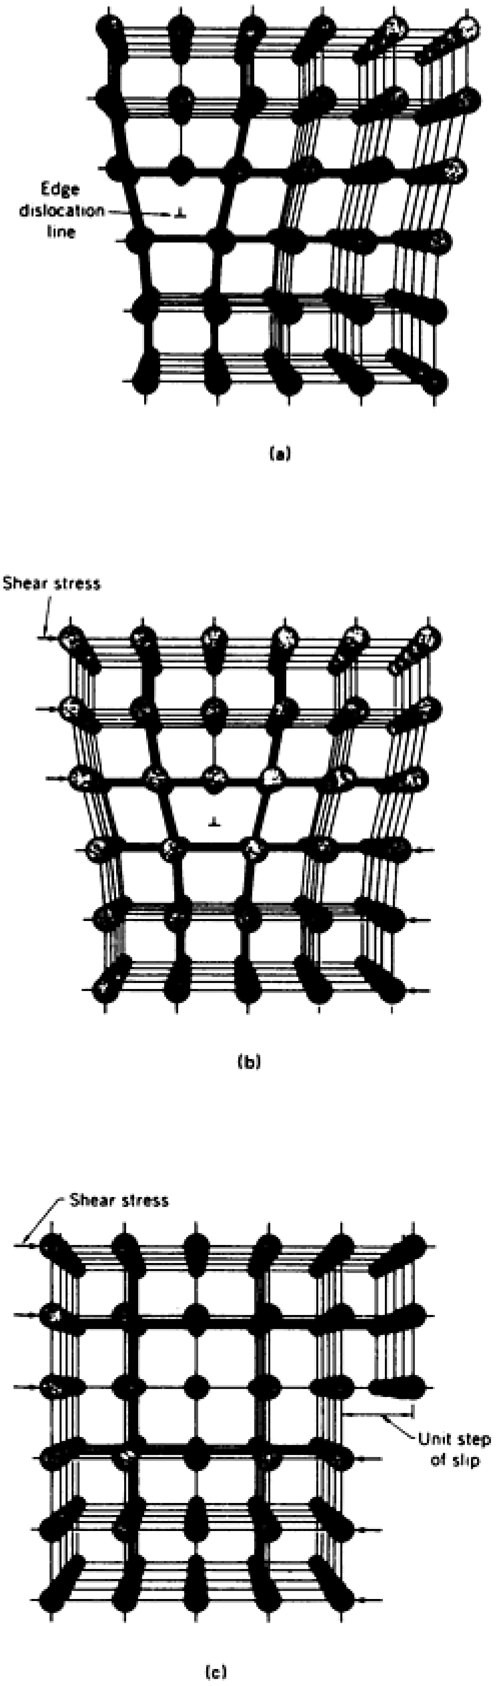

Fig. 8 The motion of an edge dislocation and the production of a unit step of slip at the surface of the crystal. (a) An edge dislocation in a crystal. (b) The dislocation has moved one lattice spacing due to the shearing force. (c) The dislocation has reached the edge crystal and produced unit slip. Adapted from Ref 4

In hexagonal close-packed crystals, the prominent slip plane is the close-packed (001) plane, and the slip directions in this plane are the close-packed directions, of which there are three nonparallel, identical choices. Thus, this crystal structure exhibits three slip systems. In the face-centered cubic structure, the slip plane is also the close-packed plane {111}. However, in this system there are four types of nonparallel {111} planes. In each plane there are three possible slip directions (<110> type), and hence 12 slip systems. In the body-centered cubic structure, the slip plane is of the {110} type (also the most closely packed plane in this system) of which there are six, and the slip directions are of the <111> type, of which there are two in each plane. Thus, the body-centered cubic structure also has 12 slip systems. The types of slip plane and slip direction are sensitive to temperature, and in some alloys other slip systems are activated when temperature changes.

Effect of Cold Working on Properties and Microstructure. The multiplication of dislocations on several slip systems upon plastic deformation leads to their interaction with each other, and this restricts their movement, so that further deformation requires an increase in external load. Thus, the material work (or strain) hardens. This effect is illustrated in Fig. 9, which shows the strengthening induced by deformation in rolling of pure copper, and of copper-zinc solid-solution alloys, at 25 °C (77 °F). Plastic deformation such that strengthening or hardening occurs is called *cold working*; plastic deformation such that work hardening does not occur is called *hot working*. (Alternative definitions are given below, under "Hot Working.") Note that these definitions have no particular attachment to room temperature.

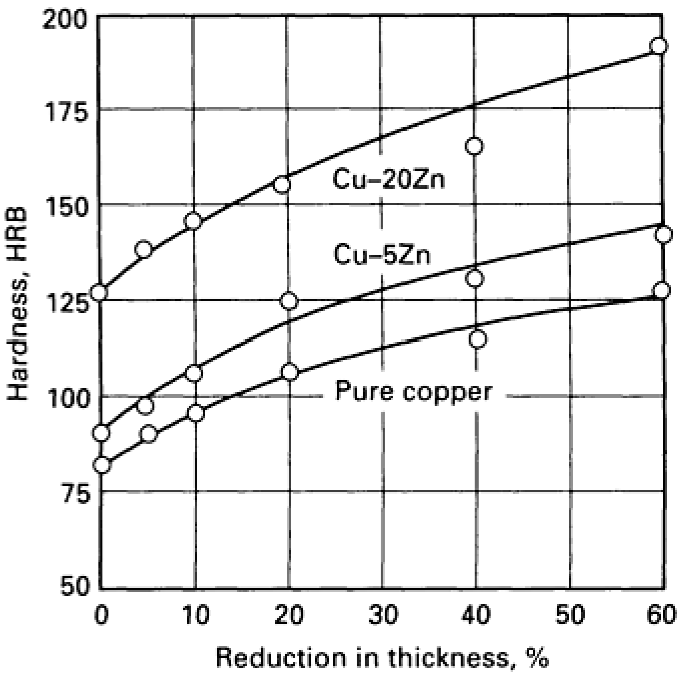

Fig. 9 The effect of plastic deformation (by rolling at 25 °C, or 77 °F) on hardness of pure copper and two Cu-Zn solid-solution alloys. Source: Ref 5

Cold working increases hardness, yield strength, and tensile strength, and lowers ductility. It also increases electrical resistivity because the increasing density of dislocations scatters the electrons. Figure 10 illustrates the effects of cold working on several properties.

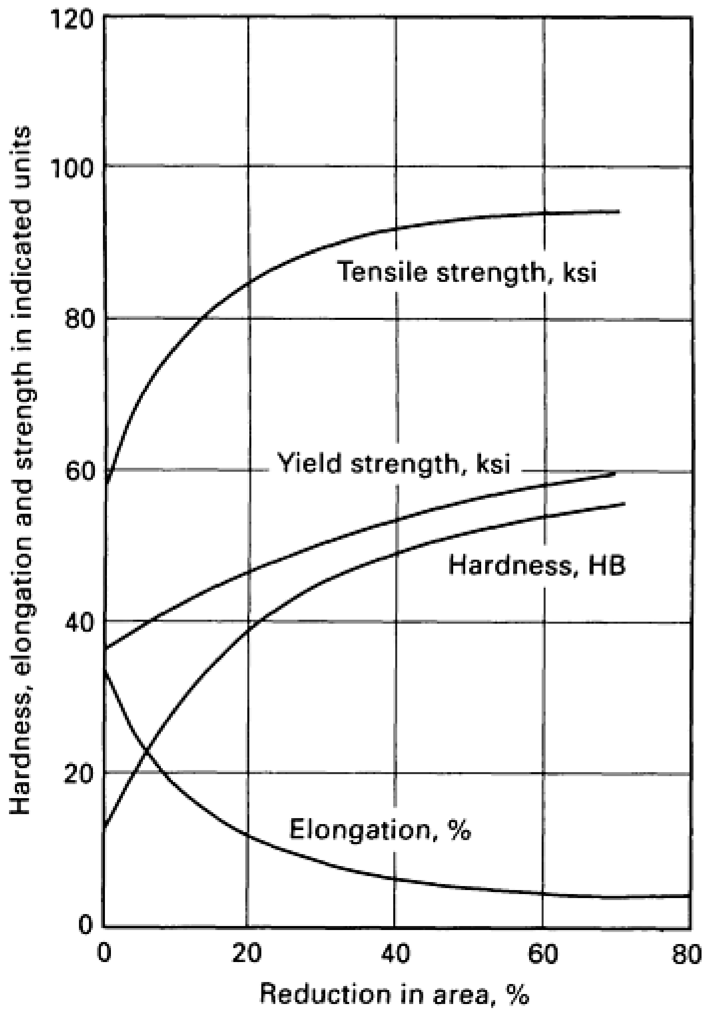

Fig. 10 The effect of cold working (by rolling at 25 °C, or 77 °F) on the tensile mechanical properties and hardness of oxygen-free, high-conductivity (OFHC) copper. Adapted from Ref 6

Cold working of a metal causes distortion of grains, and the specific nature of this distortion depends on the type of deformation (for example, rolling, swaging, and so on). If the plane of observation is parallel to the rolling direction, the grains will appear elongated in the rolling direction. Also observed in the microstructure are parallel striations within the grains, the density of which increases with the amount of deformation. These striations are actually rows of etch pits, or etched grooves, where the etchant has removed metal preferentially at surface locations at which the dislocations emerge. Such striations are sometimes called *deformation bands.* In metals and alloys which show annealing twins (mainly face-centered cubic metals, such as copper and brass), the twins, originally appearing as straight lines crossing (or nearly crossing) the grains, become bent, distorted, and fragmented. All of these microstructural features of cold worked metals are illustrated in Fig. 11.

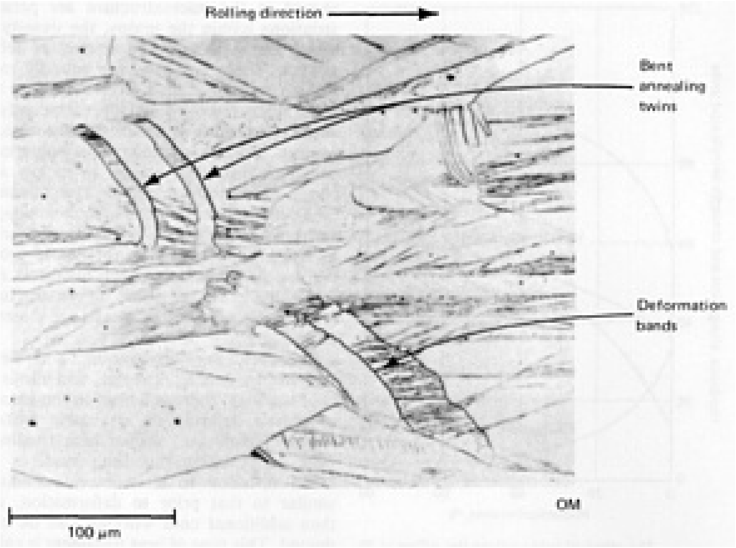

Fig. 11 The microstructure of a Cu-5Zn alloy cold rolled at 25 °C (77 °F) to a 40% reduction in thickness, showing deformation bands and bent annealing twins revealed by etching the polished surface. The features marked "Bent annealing twins" are not mechanical twins. Before cold working, straight annealing twins become bent and curved due to slip occurring across them, thus producing bent annealing twins. In this type of copper-base solid solution, mechanical twins are very difficult to form, requiring high deformation rates (for example, explosive forming). OM, optical micrograph. Source: Ref 5

Recovery, Recrystallization, and Grain Growth. In shaping of metals and alloys by cold working, there is a limit to the amount of plastic deformation attainable without fracture. However, proper heat treatment prior to reaching this limit restores the metal or alloy to a structural condition similar to that prior to deformation, and then additional cold working can be conducted. This type of heat treatment is called *annealing*, and in this section some of the principles involved and the effects which occur are summarized.

Because cold working produces an increasing concentration of lattice defects (for example, dislocations), the energy of the crystals is increased. Thus, there is a thermodynamic driving force for the metal to undergo changes which will return it to the original, low-energy condition. The rates of these changes depend on the mechanisms involved, and are sensitive functions of temperature and alloy.

The changes in strength that occur during annealing are illustrated by the hardness data in Fig. 12(a). The hardness (and the yield and tensile strengths) initially remains approximately constant (or increases slightly), then shows an abrupt decrease, followed by a continued, but gradual, decrease. The data shown in Fig. 12(a) are for a fixed temperature. A similar result is obtained by annealing samples for a fixed time at increasing temperatures, as shown in Fig. 12(b).

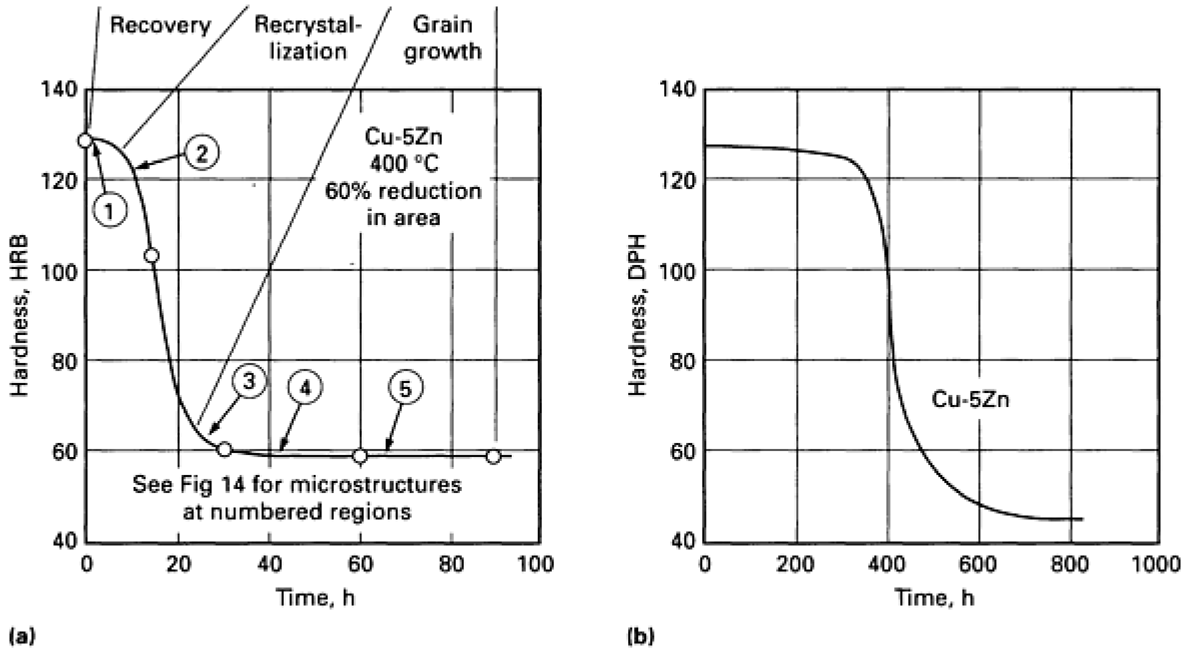

Fig. 12 (a) Effect of annealing time at fixed temperature (400 °C, or 750 °F) on hardness of a Cu-5Zn solid-solution alloy cold worked 60%. (b) Effect of annealing temperature at fixed time (15 min) on hardness of a Cu-5Zn solid-solution alloy cold worked 60%

The stage of annealing for short times or at low temperatures wherein the hardness remains constant, or increases slightly, is called the *recovery region*. Here the dislocations undergo movement by thermal activation, being rearranged into arrays somewhat more stable and more difficult to move than in the cold worked, unannealed condition, and hence cause a slight increase in hardness. In this period, such rearrangement allows some properties to attain their values prior to cold working, and hence is referred to as recovery. One such property is electrical resistivity, as illustrated in Fig. 13. The cellular arrangement of the dislocations, compared with that of the cold worked condition, increases the mean free path of the electrons and lowers the resistance.

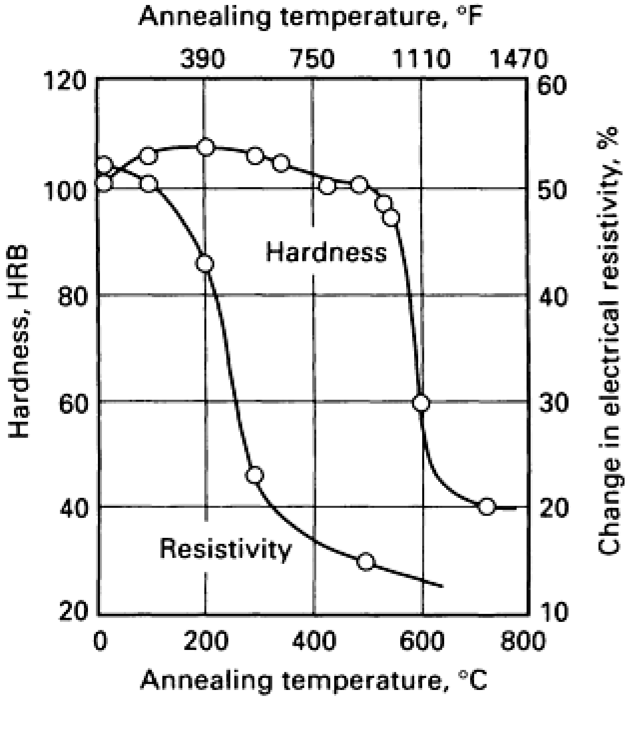

Fig. 13 Effect of annealing temperature on hardness and electrical resistivity of nickel. The metal has been cold worked at 25 °C (77 °F) almost to fracture. Annealing time, 1 h. Adapted from Ref 7

After longer times or at higher temperatures, the structure undergoes a more radical change. Small crystals appear which contain a low dislocation density (of magnitude similar to that prior to cold working) and hence are relatively soft. These crystals nucleate in regions of high dislocation density, and thus in the microstructure appear at or near deformation bands. With time, these nuclei grow, and more nuclei form in the remaining cold worked matrix. Eventually, these grains contact each other (at that time the original worked material has disappeared). The formation of these grains is referred to as *recrystallization.* During this recrystallization period, strength decreases drastically (Fig. 12 and 13).

Following recrystallization, the energy of the alloy is reduced further by a decrease in the grain-boundary area by grain growth. Thus, the long-time or high-temperature region of the annealing curve is referred to as grain growth. Because strength decreases as grain size increases, during this period the hardness decreases, although only gradually (Fig. 12a).

The microstructural changes which occur during annealing are illustrated in Fig. 14. During recovery, there is a decrease in the density of deformation bands, although this effect is not prominent. When crystallization commences, small, equiaxed grains begin to appear (see micrograph 2 in Fig. 14 and Fig. 15) in the structure. These continue to form and grow until the cold worked matrix is consumed, which marks the end of the recrystallization period and the beginning of grain growth. Further annealing causes only an increase in grain size (see micrographs 3, 4, and 5 in Fig. 14).

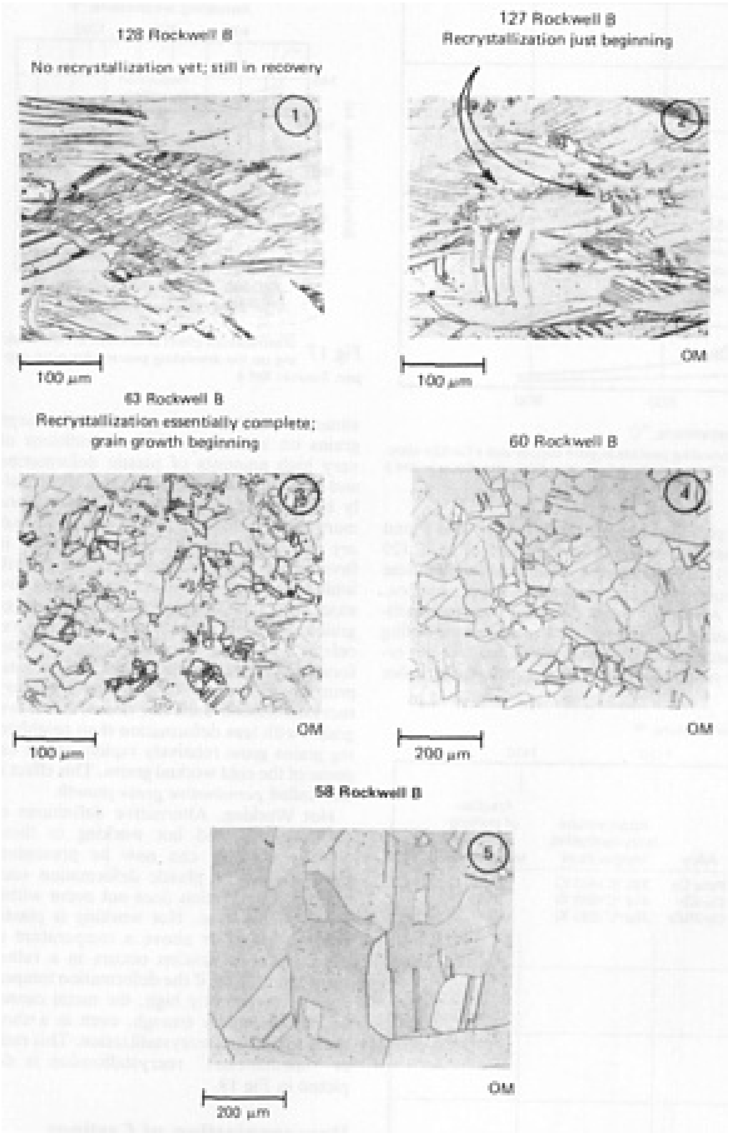

Fig. 14 Microstructure of a Cu-5Zn alloy, cold rolled to 60%, then annealed for different times at 400 °C (750 °F). The numbers refer to the different annealing times shown in Fig. 12(a). Source: Ref 5

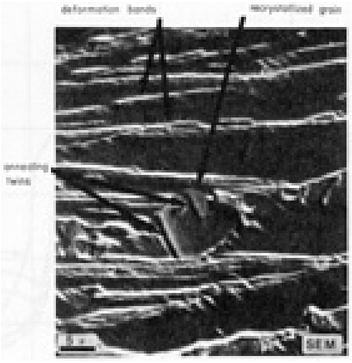

Fig. 15 High-magnification scanning electron micrograph showing a small recrystallized nucleus. Cu-5Zn alloy, cold worked by rolling 20 °C (68 °F) to reduction in thickness of 60%; annealed 60 min at 350 °C (660 °F). Source: Ref 5

Factors Affecting Recrystallization. Because annealing of cold worked metals is usually carried out to soften the material, the temperature and time required to complete recrystallization must be known in order to determine the proper heat treatment. It is common to refer to the recrystallization temperature as an indicator of the temperature at which the metal must be annealed for softening. (This temperature can be taken to be that which gives any specified amount of recrystallization.)

Several factors affect the value of the recrystallization temperature. Two of the most important are annealing time and amount of prior cold work. Figure 16 illustrates the effect of annealing time. The longer the time at a given temperature, the farther the metal progresses in the annealing process. Thus, if a metal just commences recrystallization at 200 °C (400 °F) in 15 min, then it may be completely recrystallized in 30 min.

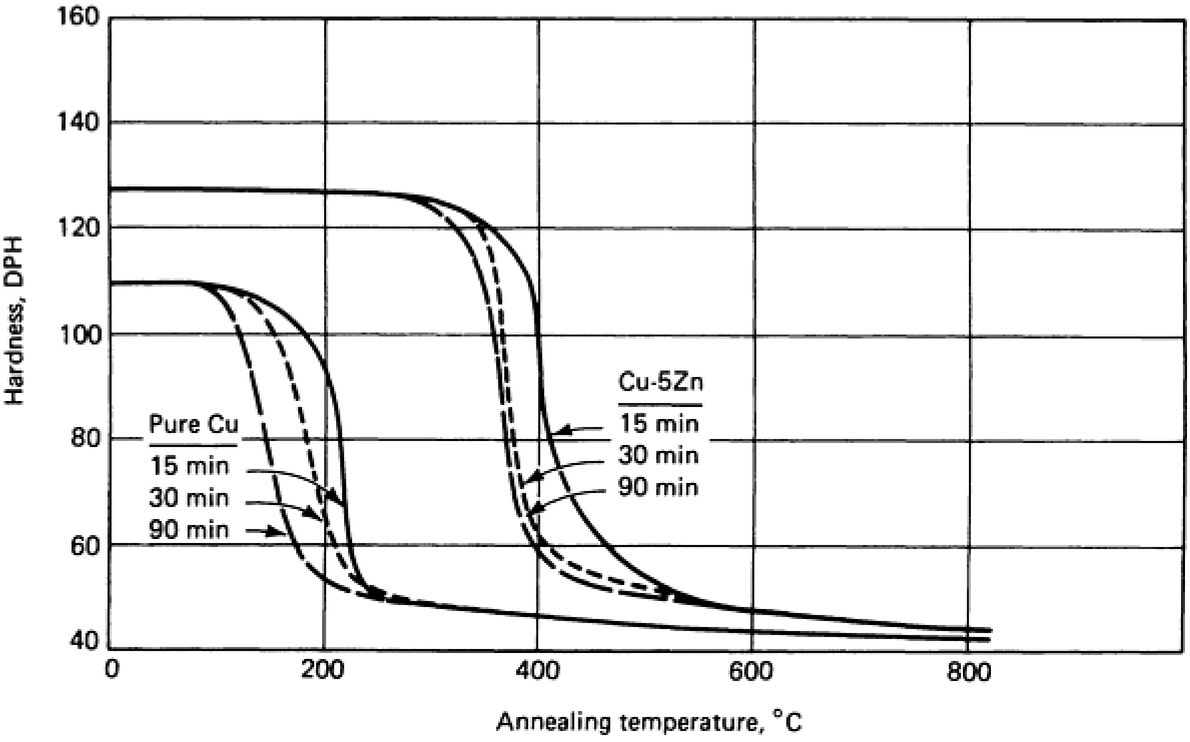

Fig. 16 Illustration of the effect of annealing time on the annealing process in pure copper and a Cu-5Zn alloy. Both materials were originally cold rolled at 25 °C (77 °F) to 60% reduction in thickness. Source: Ref 5

The effect of the amount of prior cold work is illustrated in Fig. 17. Increasing amounts of plastic deformation increase the concentration of lattice defects (for example, dislocations) and make the metal more thermodynamically unstable. Hence, recrystallization occurs at lower temperatures, or in shorter times, the greater the amount of cold work. Although this is the main effect, it is to be noted that the type of deformation, the rate of deformation, and the deformation temperature also affect the rate of recrystallization.

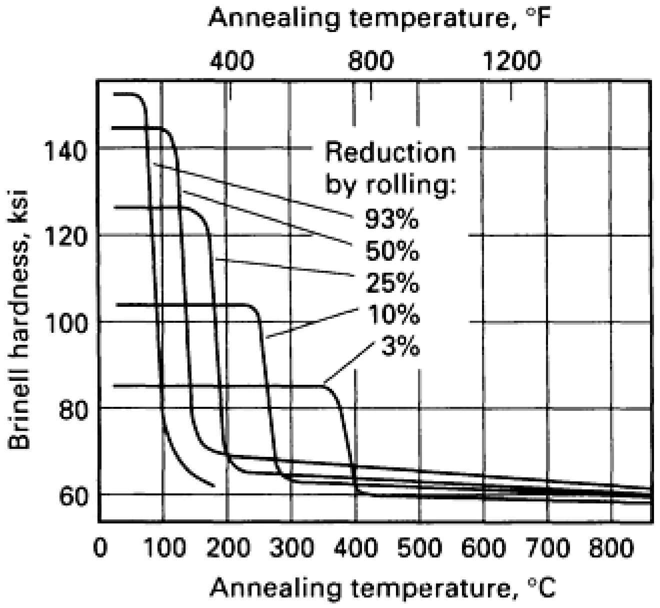

Fig. 17 Illustration of effect of amount of cold working on the annealing process for pure copper. Source: Ref 8

Chemical composition affects the recrystallization process, and here a distinction must be made between solid-solution alloys and multiphase alloys. In many alloys containing second-phase particles, the presence of such particles favors formation of recrystallization nuclei and thus lowers the recrystallization temperature. In solid-solution alloys, even quite small amounts of solute can have potent effects on the recrystallization temperature. For example, addition of 0.05% Ag to copper will increase the recrystallization temperature from about 140 °C (285 °F) to about 340 °C (645 °F). Thus, because silver only slightly lowers the electrical conductivity of copper, this alloy is used in applications which require the alloy to be cold worked for strength but in which slight heating may occur, and stress relaxation and recrystallization must be prevented.

If the solubility is sufficiently high to allow considerable solute concentration, the recrystallization temperature may decrease. This is illustrated in Fig. 18 for Cu-Zn alloys. This effect is expected to be related to the influence of zinc on the atom mobility in Cu-Zn alloys, and indeed the activation energy, Q, for diffusion in these alloys increases slightly with additions of up to 10% Zn, then decreases considerably with additions from 10 to 20% Zn.

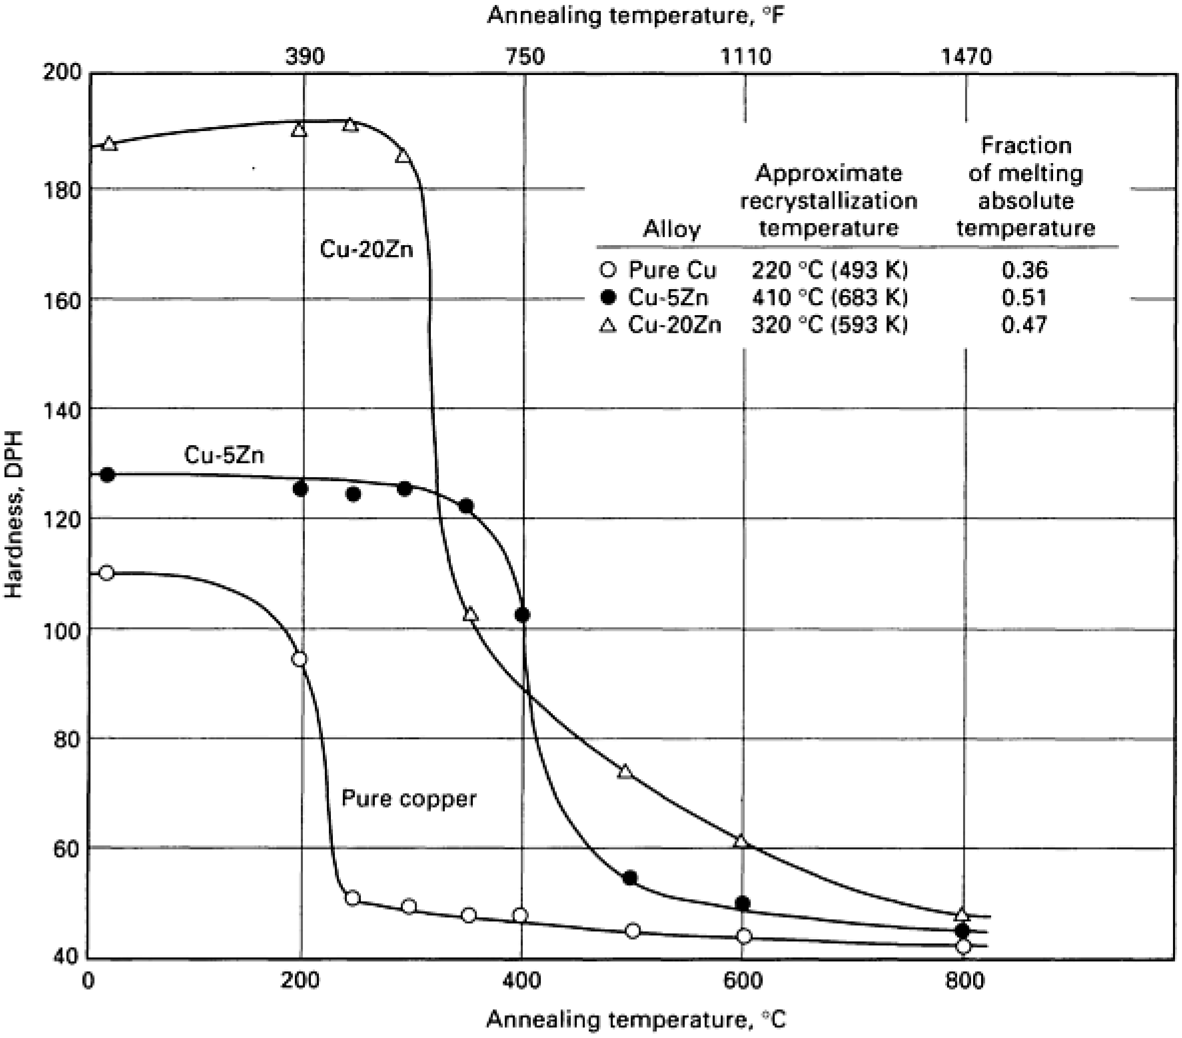

Fig. 18 Illustration of effect of zinc content of Cu-Zn solid-solution alloys on the annealing process. The alloys were originally cold rolled at 25 °C (77 °F) to 60% reduction in thickness. The recrystallization temperatures listed are based on the inflection point of each curve. Source: Ref 5

It is useful here to note a rule of thumb--that the recrystallization temperature is approximately 0.3 to 0.6 of the absolute melting point. In the case of Cu-Zn solid-solution alloys, addition of zinc to copper lowers the melting point, and thus the recrystallization temperature will decrease for high zinc contents (for example, 20 to 30%) (see Fig. 18).

Because recovery, recrystallization and grain-growth processes all involve atom movement, it is expected that the rates of these processes will depend on temperature in the same functional relation as does diffusion--that is, the rate is proportional to $e^{-Q/RT}$, where Q is the activation energy for the particular process. Thus, we may take as an approximation that the time required at a given temperature for recrystallization to commence (or for any given amount of recrystallization to be attained) will be inversely proportional to this exponential expression. Using as typical activation energies those given for diffusion, it is found that a decrease in temperature of 10 °C (20 °F) may increase by a factor of two the time required for recrystailization to commence.

Abnormal Grain Growth. The recrystallization process referred to in the preceding discussions is sometimes called *primary recrystallization*, to distinguish from other situations which lead to unusually large grains on annealing. Under conditions of very high amounts of plastic deformation and high annealing temperatures, abnormally large grains can develop following primary recrystallization: this is called *secondary recrystallization.* Such behavior is favored by the presence of grain-growth inhibitors, such as insoluble particles (for example, inclusions). Abnormally large grains can also form if the metal has received a critical, but small, amount of deformation (for example, about 10% or less) prior to annealing. In this case, primary recrystallization does not occur, but a few grains with less deformation than neighboring

grains grow relatively rapidly at the expense of the cold worked grains. This effect is also called *germinative grain growth.*

Hot Working. Alternative definitions of cold working and hot working to those given previously can now be presented. Cold working is plastic deformation such that recrystallization does not occur within a reasonable time. Hot working is plastic deformation at or above a temperature at which recrystallization occurs in a rather short time. Thus, if the deformation temperature is sufficiently high, the metal cannot be cooled rapidly enough, even in a short time, to prevent recrystallization. This rather "spontaneous" recrystallization is depicted in Fig. 19.

Homogenization of Castings

One of the most important commercial heat treatments is homogenization of castings. Such a treatment is used prior to mechanical processing of the cast ingot, and it is often used even when an object is cast into essentially the final shape. The temperatures and times used depend on the diffusion rate and the starting structure (the latter dictates the concentration gradients and the diffusion path). To understand how this enters into the situation, it is important to know how solidification occurs in alloys, and especially how chemical segregation develops during solidification.

Dendrite Formation. In metals and alloys, the crystals which form in the liquid during freezing generally have a configuration consisting of a main branch with many appendages. A crystal of such a morphology is called a dendrite ("fern-like"), and its formation is illustrated schematically in Fig. 20. During freezing, many crystals form, usually on the cold sidewalls of the mold, but also in the center of the casting. As these dendritic crystals grow, they eventually become large enough so that impingement occurs. Then the remaining liquid freezes, with a boundary formed between the

differently oriented grains. The original dendritic pattern may not be apparent by observation of only the geometry of the grain boundaries outlining the grains.

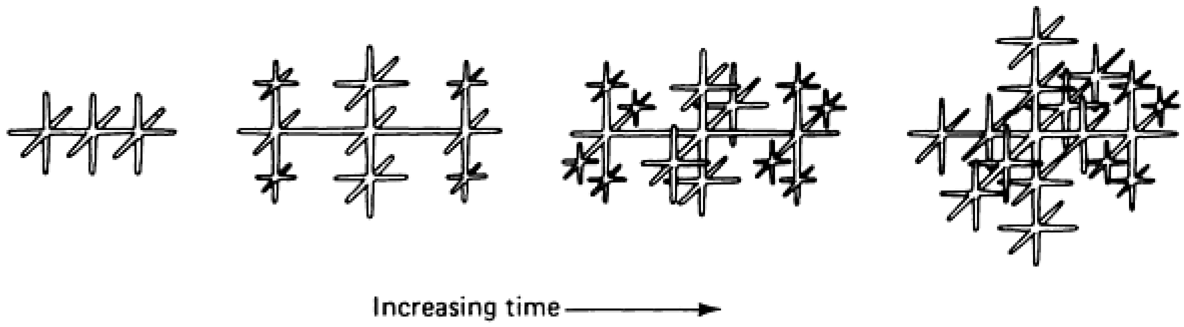

Fig. 20 Schematic illustration of a dendritic crystal forming in a liquid. Adapted from Ref 10

Coring. In solidification of most alloys, chemical segregation intrinsically accompanies dendrite formation. To see how this develops, consider a hypothetical alloy whose phase diagram is that shown in Fig. 21. On slow cooling of a liquid alloy containing 30% B, crystallization commences at temperature T_0. The chemical composition of this crystal will be 10% B. As cooling continues, the crystal grows in size (as a dendrite). The phase diagram shows that the equilibrium composition of the crystal must follow the solidus line (line abc in Fig. 21). Thus, the crystal continuously changes its chemical composition, approaching 30% B as the temperature approaches that of completion of freezing, T_2. At T_2, the metal consists of crystals each containing uniformly 30% B. Note that the center of each crystal corresponds to the original nucleus, which had only 10% B when freezing commenced. Thus, on cooling, as the dendrites increased in size, from each layer frozen onto the crystal some B atoms must move throughout the crystal, including some to the center, to maintain the chemical composition uniformly at the value given by the solidus at any given temperature.

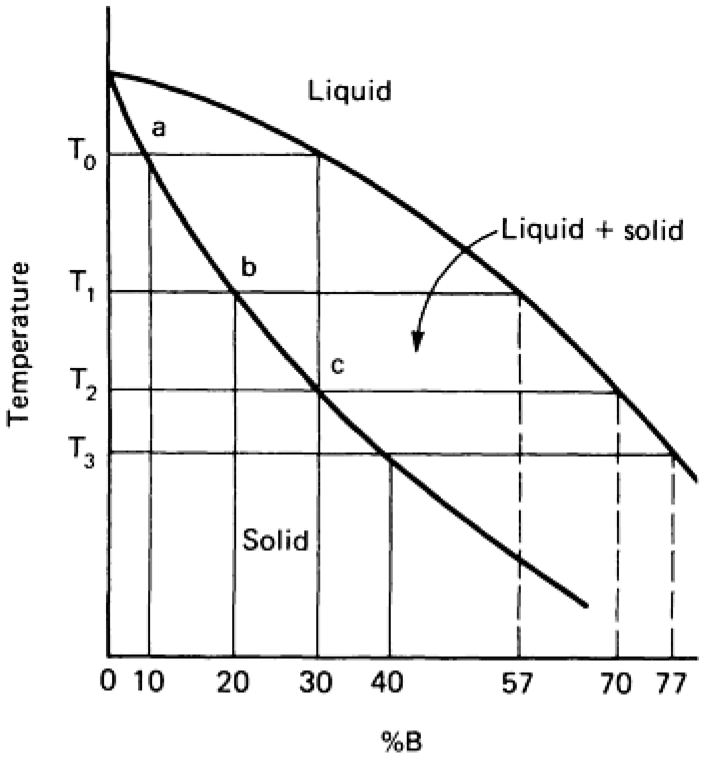

Fig. 21 Hypothetical phase diagram of system A-B, showing the composition of the solid as a 30% B alloy

freezes. Adapted from Ref 5

Clearly, such atom movements require finite time, and the question naturally arises as to what deviations from equilibrium will occur if the alloy is cooled rapidly from the liquid. A simplified picture of what occurs is as follows. On rapid cooling, the first crystals to form have a composition of 10% B. As these grow, the interface between the liquid and the solid crystals maintains the chemical composition given in the phase diagram. Thus, when the crystal has grown as the temperature has decreased from T_0 to T_1, the outside of the crystal will have a composition of 20% B. However, due to the rapid cooling, the center of the crystal will still be 10% B. Between the center and the outside, the composition varies smoothly between 10 and 20% B. The rapid cooling has not allowed sufficient time for significant diffusion to occur in this composition gradient. On slow cooling, freezing would be complete when the temperature reached T_2. However, at this temperature the outside of the crystal has a composition of 30% B, but the center only 10% B. Thus the average composition of the crystal is somewhere between 10 and 30% B. Freezing cannot be complete until the average composition reaches 30% B (because this is the composition of the alloy), and hence under-cooling occurs. Layers continue to add to the dendrite, until the sidearms impinge, and finally all of the dendrites impinge on each other, and freezing is complete. In the example used here, the last layer to freeze, when the sidearms make contact, contains 40% B (Fig. 21).

The frozen structure consists of dendrites in which the central regions of the main branch and of the sidearms contain about 10% B, and the regions where the sidearms met on completion of freezing contain about 40% B. If an etchant is used for which the rate of attack of the metal is sensitive to this compositional difference, then certain regions will be dissolved or attacked more readily than others. The surface then will consist of low and high regions, which reflect light differently, causing contrast in the appearance of the microstructure. An example is shown in Fig. 22 for a Ni-Cu alloy containing 30% Cu. Note that at low magnification the uneven etching has revealed the dendritic structure of the crystals.

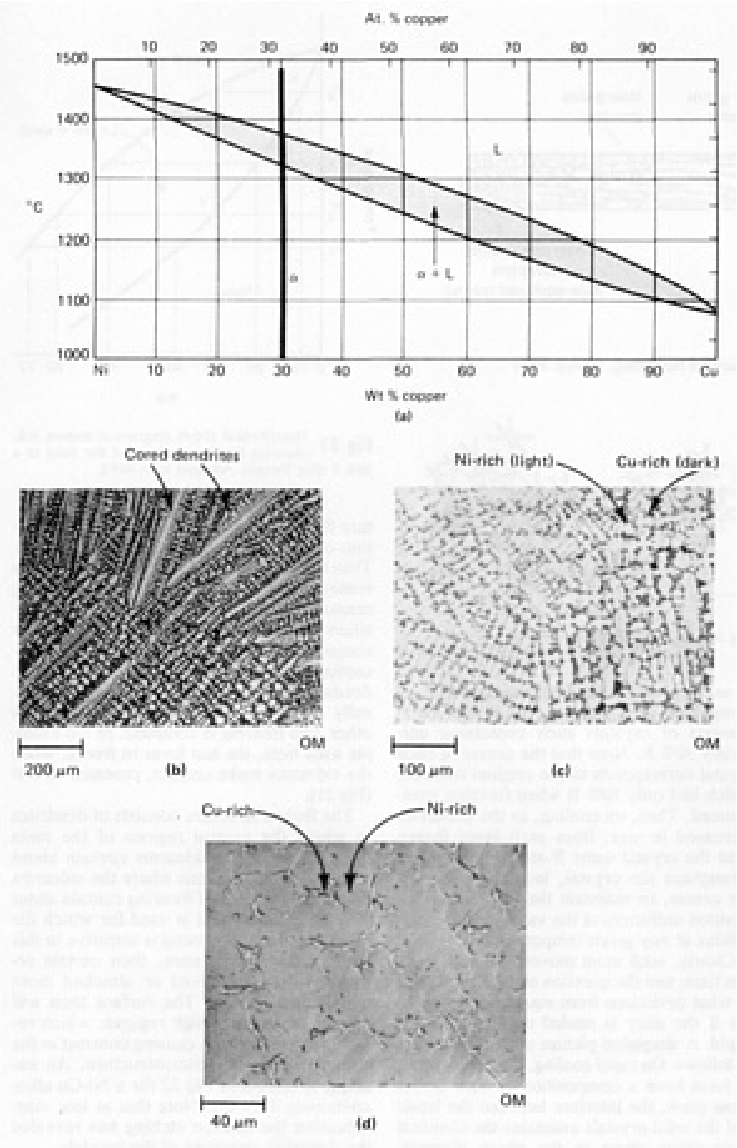

Fig. 22 The Ni-Cu phase diagram and the microstructure of a Ni-30Cu alloy that has been cooled rapidly from the liquid, developing a nonequilibrium cored structure. (a) Ni-Cu phase diagram. (b), (c), (d) The microstructure at increasingly higher magnifications. Note that the dendrite cells are approximately 40 μm across (d). Source: Ref 5

This chemically segregated, dendritic structure is referred to as cored, and the process of its formation is called coring.

Chemical Homogenization Annealing. The chemical gradients in a dendritically cored structure can be reduced to an acceptable level by annealing at a sufficiently high temperature for a sufficient time. The rate of diffusion is given by an appropriate solution to Fick's law. As a conservative approximation, the required time is $x^2 \cong Dt$, where x is the distance between the regions of low and of high concentration in the dendrite cell, which is one-half of the cell size. As an example, in Fig. 22(d) the cell size is approximately 40 μm, so x = 20 μm. Taking $D = 2 \times 10^{-10}$ cm^2/s at 1000 °C (1273 K) for a Ni-30Cu alloy, then the required homogenization time is about 6 h. At 1100 °C (1373 K), $D = 10^{-9}$, and the required time is 1 h. Obviously, higher temperatures lower considerably the required time, but other factors, such as excessive oxidation, must be considered.

If an ingot with a cored, cast structure, such as that shown in Fig. 22, is reduced in thickness 50% by rolling, then the dendritic cells will (on the average) be elongated in the rolling direction but reduced in thickness 50% in the through-thickness direction of the rolled plate. Thus the effective diffusion distance x becomes about 10 μm (0.4 mil). Then, at 1000 °C (1830 °F), the required homogenization annealing time becomes about 1 h, instead of the 6 h for the as-cast

structure. This points out the advantage in processing of coupling a homogenization anneal with plastic deformation to remove coring present in the as-cast structure.

In many alloy ingots, there also occurs gross, or ingot, segregation, where the chemical composition of the outside of the ingot may be different from that along its center-line. Here the final liquid freezes, and rejection of solute elements (frequently impurities) from the advancing front of the freezing crystals, in which they have a lower solubility, results in a region rich in these elements near the center. However, a calculation similar to that above shows that the diffusion distance in this type of chemical inhomogeneity is much too great to be reduced appreciably by homogenization annealing.

In many commercial nonferrous alloys, the as-cast structure will not only be cored, but also will contain nonequilibrium, second-phase particles. In such systems, on slow cooling, when freezing is complete a single-phase solid will be present (as described above). However, on rapid cooling in which coring occurs, the liquid composition may increase to the value of the eutectic before freezing is completed. Then this liquid freezes to a solid eutectic structure. The microstructure then consists of a dendritically cored matrix containing small regions of multiphase, eutectic solid. These regions will dissolve on proper solution heat treatment, and thus will be removed along with the coring.

Precipitation Hardening Heat Treatments

In designing alloys for strength, an approach often taken is to develop an alloy in which the structure consists of particles which impede dislocation motion dispersed in a ductile matrix. The finer the dispersion, for the same amount of particles, the stronger the material.

Such a dispersion can be obtained by choosing an alloy which, at elevated temperature, is single phase, but which on cooling will precipitate another phase in the matrix. A heat treatment is then developed to give the desired distribution of the precipitate in the matrix. If hardening occurs from this structure, then the process is called precipitation hardening or age hardening. It is to be noted that not all alloys in which such a dispersion can be developed will harden.

The mechanism of strengthening by precipitation hardening involves the formation of coherent clusters of solute atoms (that is, the solute atoms have collected into a cluster but still have the same crystal structure as the solvent phase). This causes a great deal of strain because of mismatch in size between the solvent and solute atoms. The cluster stabilizes dislocations, because dislocations tend to reduce the strain, similar to the reduction in strain energy of a single solute atom by a dislocation. When dislocations are anchored or trapped by coherent solute clusters, the alloy is considerably strengthened and hardened.

However, if the precipitates are semicoherent (sharing a dislocation-containing interface with the matrix), incoherent (sharing a disordered interface, akin to a large-angle grain boundary, with the matrix), or are incapable of reducing strain behavior because they are too strong, a dislocation can circumvent the particles only by bowing into a roughly semicircular shape between them under the action of an applied shear stress. Consequently, the presence of the precipitate particles, and even more importantly the strain fields in the matrix surrounding the coherent particles, provide higher strength by obstructing and retarding the movement of dislocations. The characteristic that determines whether a precipitate phase is coherent or noncoherent is the closeness of match or degree of disregistry between the atomic spacings on the lattice of the matrix and on that of the precipitate.

Solution Heat Treatment. A prerequisite to precipitation hardening is the ability to heat the alloy to a temperature range wherein all of the solute is dissolved, so that a single-phase structure is attained. This is shown schematically in Fig. 23 for a 10% B alloy in a hypothetical system A-B. Heating above the solvus temperature T_2 for this alloy, and holding in the α range for sufficient time, will form the single phase α. This is the required solution heat treatment. This structure is then retained at ambient temperatures by cooling rapidly (for example, water quenching) from the α range to prevent the precipitate from forming. The structure is supersaturated with respect to the solute, and hence is unstable.

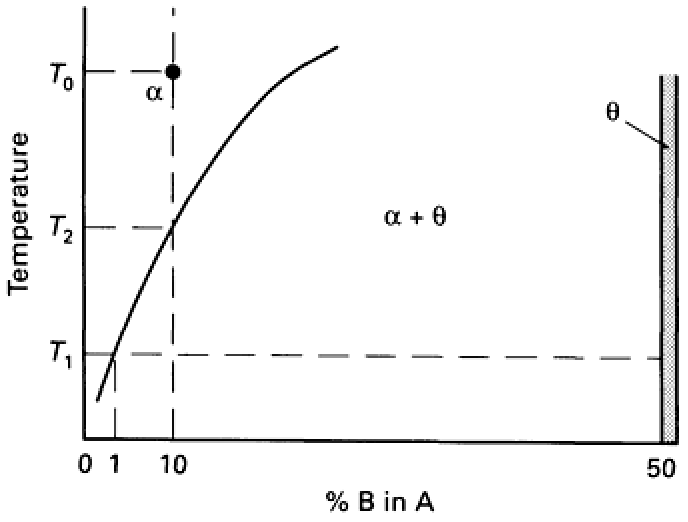

Fig. 23 Hypothetical phase diagram of system A-B. The decreasing solubility of B in α with decreasing temperature allows an alloy containing 10% B to be single-phase at high temperature (that is, above T_2) but two-phase at low temperature (T_1). Adapted from Ref 5

The Process of Precipitation. After quenching from the α region (Fig. 23), precipitation is achieved by reheating the alloy below the solvus (T_2 in Fig. 23) at a suitable temperature for a suitable time. During this time, at localized regions (for example, grain boundaries), the precipitates nucleate. Because these precipitates have a higher solute content than the matrix, the region in the matrix surrounding them is reduced in solute content. This forms a concentration gradient such that the solute atoms diffuse from the adjacent matrix toward the particles, allowing the precipitates to continue to grow. The rate of growth is diffusion-controlled and is given by an appropriate solution to Fick's law. The precipitation process is depicted schematically in Fig. 24. Here the precipitate contains 50% B (see Fig. 23).

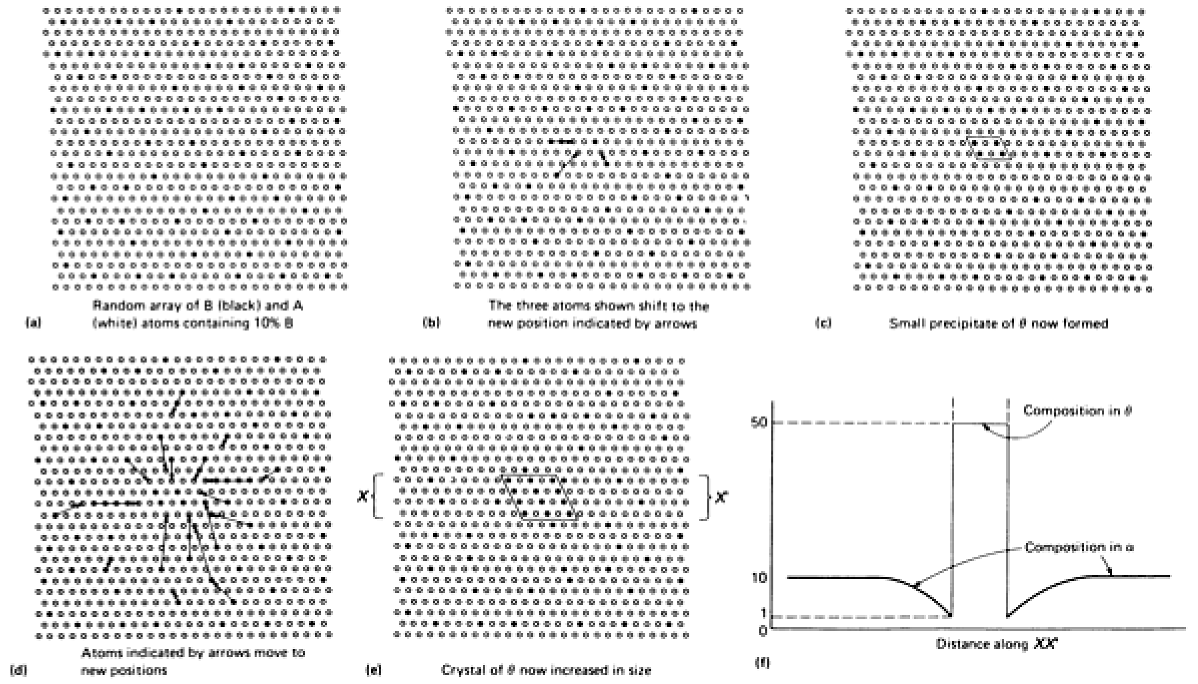

Fig. 24 Schematic illustration of formation of a precipitate in a supersaturated matrix. Time is increasing from (a) to (e), but at (e) equilibrium is not yet attained. (f) Concentration profile through the precipitate in (e). Source: Ref 5

The maximum amount of precipitate which can form is given by the equilibrium amount, which can be calculated from a mass balance (lever rule). Once this equilibrium amount of precipitate has been attained, then further change in the precipitates is caused by the tendency for the system to reduce the precipitate/matrix interfacial area. Thus, with time at a given aging temperature, the smaller precipitates dissolve, with the solute diffusing through the matrix to contribute to the growth of the larger particles. This results in a microstructure containing larger, but fewer, particles. An equivalent effect is obtained by using a high aging temperature for a given time. These changes are depicted schematically in Fig. 25.

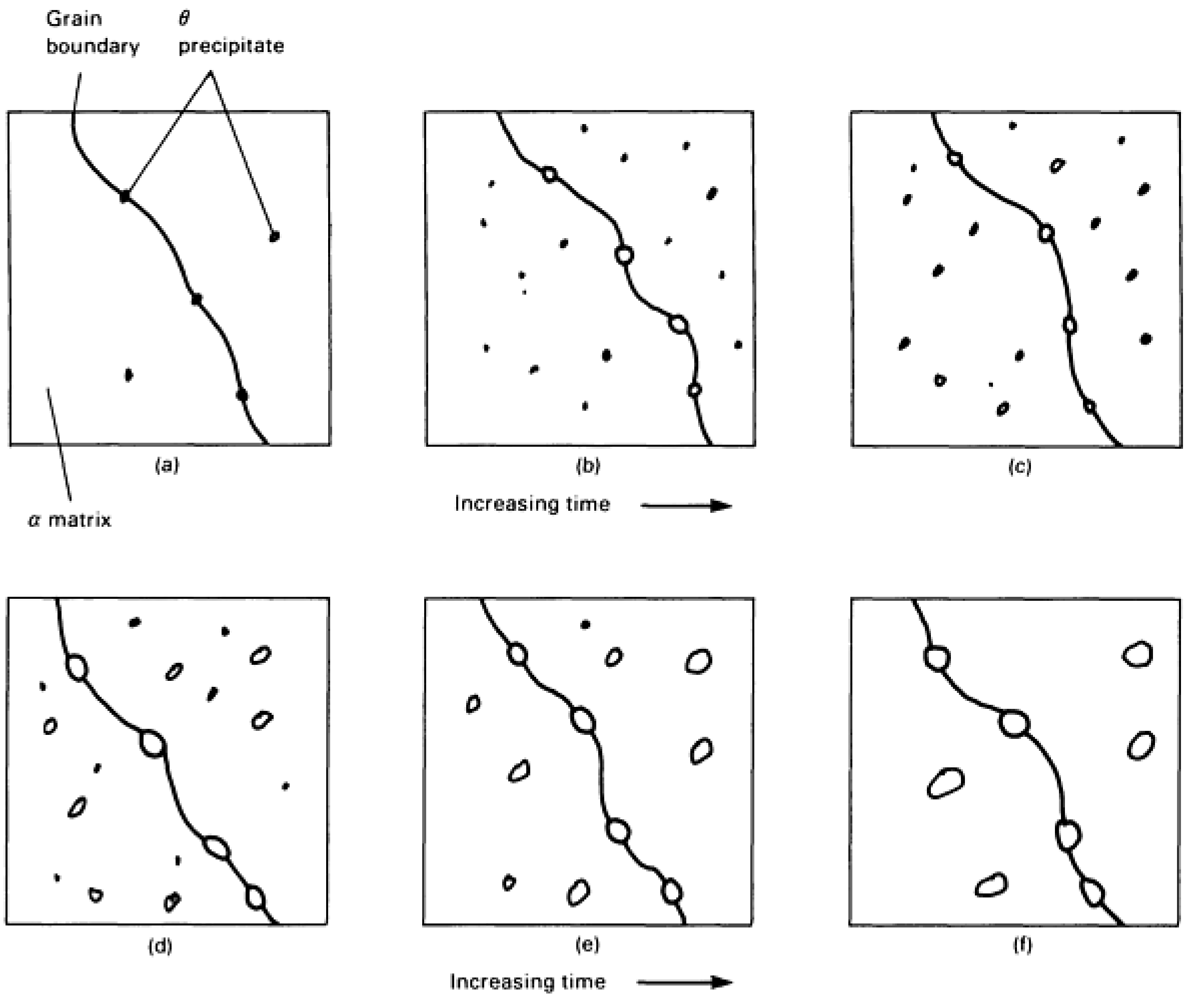

Fig. 25 Schematic illustration of formation of θ precipitates in the α matrix (a and b) and their coarsening (c to f)

Control of Precipitation through Heat Treatment. The precipitation heat treatment for the desired properties is determined empirically. Higher precipitation temperatures usually are associated with a lower nucleation rate and thus a coarser precipitate distribution. Also, as the precipitation temperature used approaches the solvus, the amount of precipitate decreases (vanishing at the solvus).

The microstructural effects will be demonstrated by referring to the aging of an Al-5Cu alloy. Figure 26 shows that this alloy must be solution heat treated at temperatures between 530 °C (986 °F) (solvus) and 560 °C (1040 °F) (solidus). If this alloy is quenched from 545 °C (1015 °F) (after 1 week), then aged for 12 h at 400 °C (750 °F), the structure obtained will be that shown in Fig. 27(a). The precipitates are fine and evenly distributed, and are about 1 μm in size. If an aging temperature of 300 °C (570 °F) is used (for 12 h), then the structure in Fig. 27(b) is obtained. It can be seen that this higher aging temperature produced a somewhat coarser distribution of θ than that at 300 °C (570 °F).

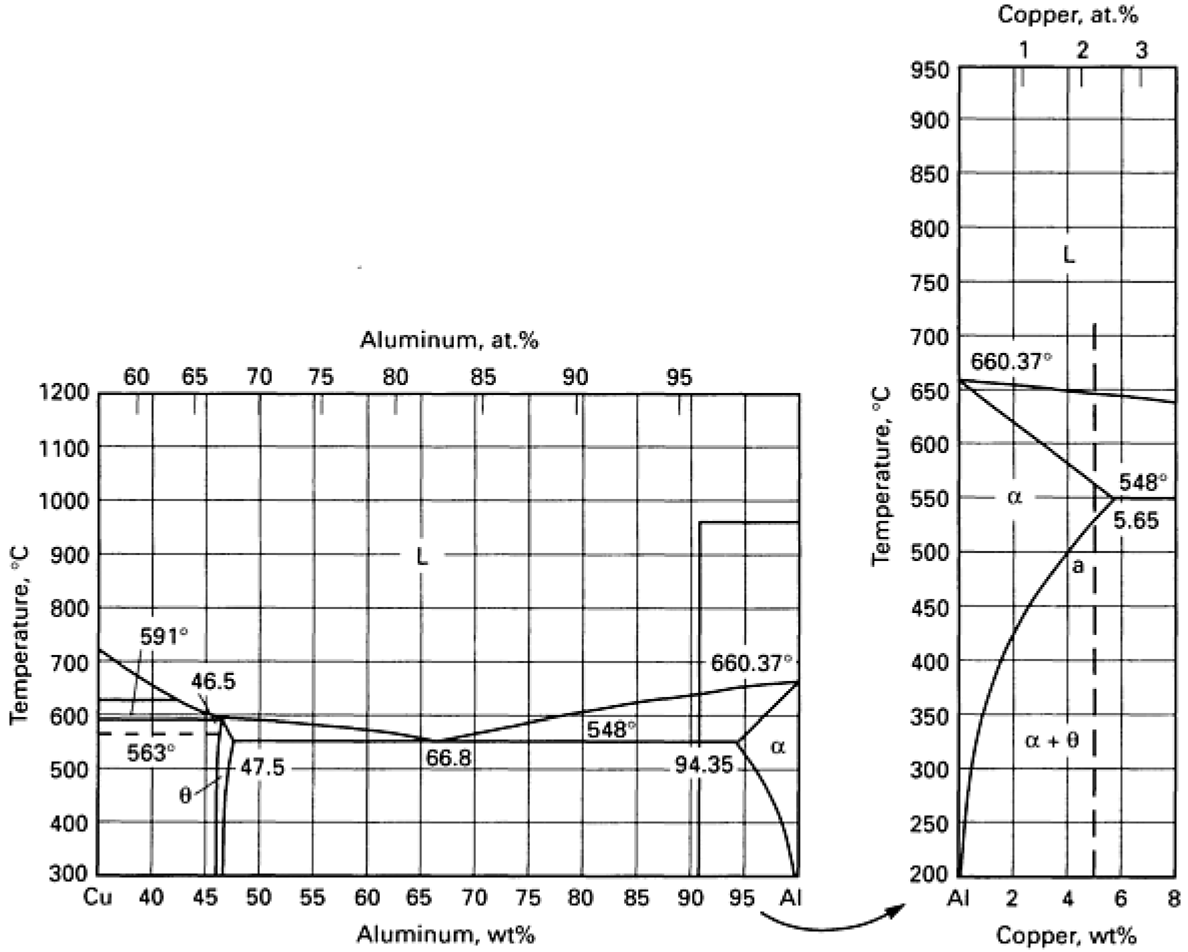

Fig. 26 The aluminum-rich end of the Al-Cu phase diagram, showing the 5% Cu line

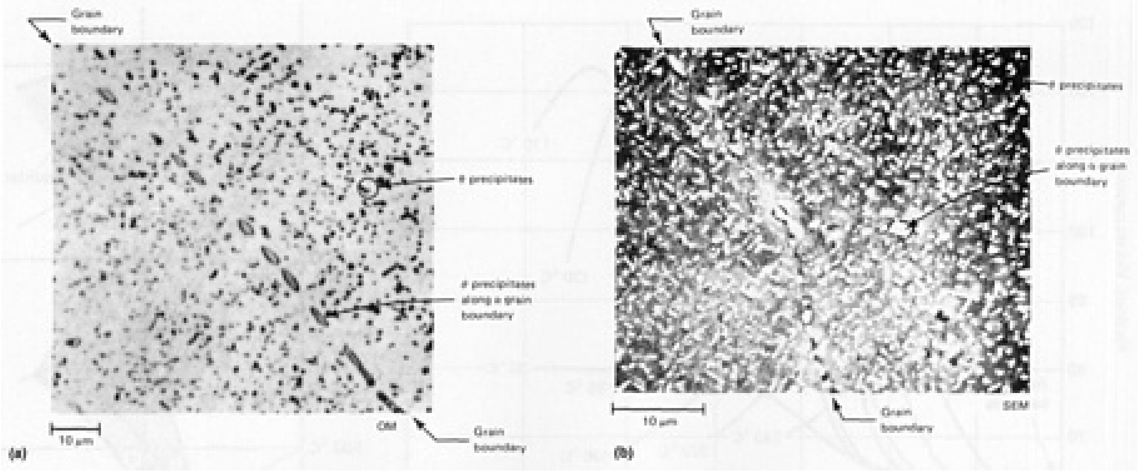

Fig. 27 Microstructure of Al-5Cu alloy heated for 1 week at 545 °C (1015 °F), cooled rapidly to 25 °C (77 °F), then held 12 h at (a) 400 °C (750 °F) and (b) 300 °C (570 °F). (a) Optical micrograph (OM). (b) Scanning electron micrograph (SEM). Source: Ref 5

In the Al-5Cu alloy (and in most other precipitation-hardenable alloys), the precipitation process is not as simple as that depicted schematically in Fig. 24. Instead, formation of the equilibrium precipitate (θ in the Al-Cu alloy) is preceded by formation of one or more nonequilibrium configurations or precipitates. For an Al-4.6Cu alloy, this is shown in Fig. 28.

In the earliest stage, Cu-rich zones form (called *Guinier-Preston Zones*), followed by two metastable precipitates (θ" and θ'), before the equilibrium θ" appears. Note how fine these metastable phases are. In Fig. 28, the θ" particles are approximately 0.01 μm in size, corresponding to particles about 50 atoms in size.

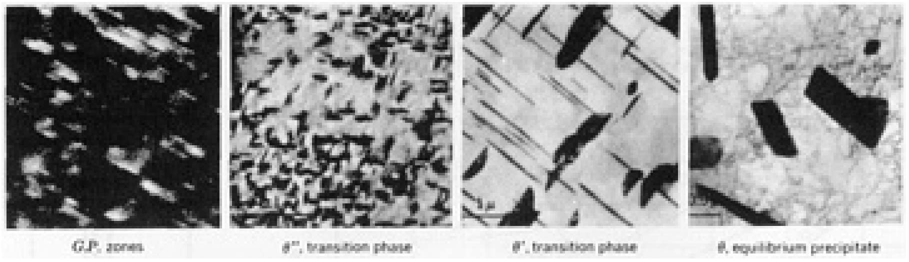

Fig. 28 Transmission electron micrographs of precipitates formed in an Al-4.6Cu alloy with increasing aging time (left to right). The micrograph at far right shows θ precipitates similar in size to those shown in Fig. 27(b). Adapted from Ref 11

Precipitation Hardening. The high strength is produced by the finely dispersed precipitates that form during precipitation treatments (which may include either natural, room-temperature aging, or artificial aging at elevated temperatures). The strengthening which occurs during aging of an Al-4Cu alloy is illustrated in Fig. 29. Note that the maximum hardness is about double that in the as-quenched (supersaturated α) condition. Also note that the maximum hardness does not correspond to formation of the equilibrium θ phase, but to the metastable, transition phases, which form in a considerably finer distribution than does θ(compare Fig. 28 and 27).

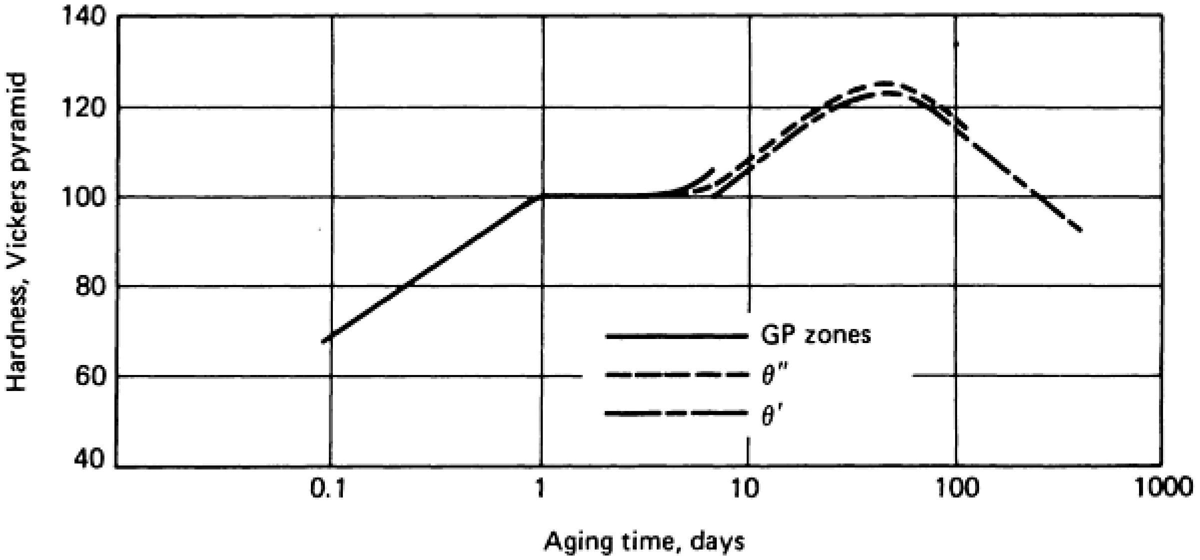

Fig. 29 Hardness curve for an Al-4Cu alloy showing the relationship between the various precipitates formed and the hardness on aging at 130 °C (265 °F). Compare this curve to the structures shown in Fig. 28. Source: Ref 5

The effect of temperature and time on aging is illustrated by the data in Fig. 30. As pointed out previously, the higher the precipitation temperature, the lower the maximum hardness, because less precipitate forms as the solvus temperature is approached. However, the higher the temperature, the higher the rate of precipitation, and hence the maximum hardness is attained in less time.

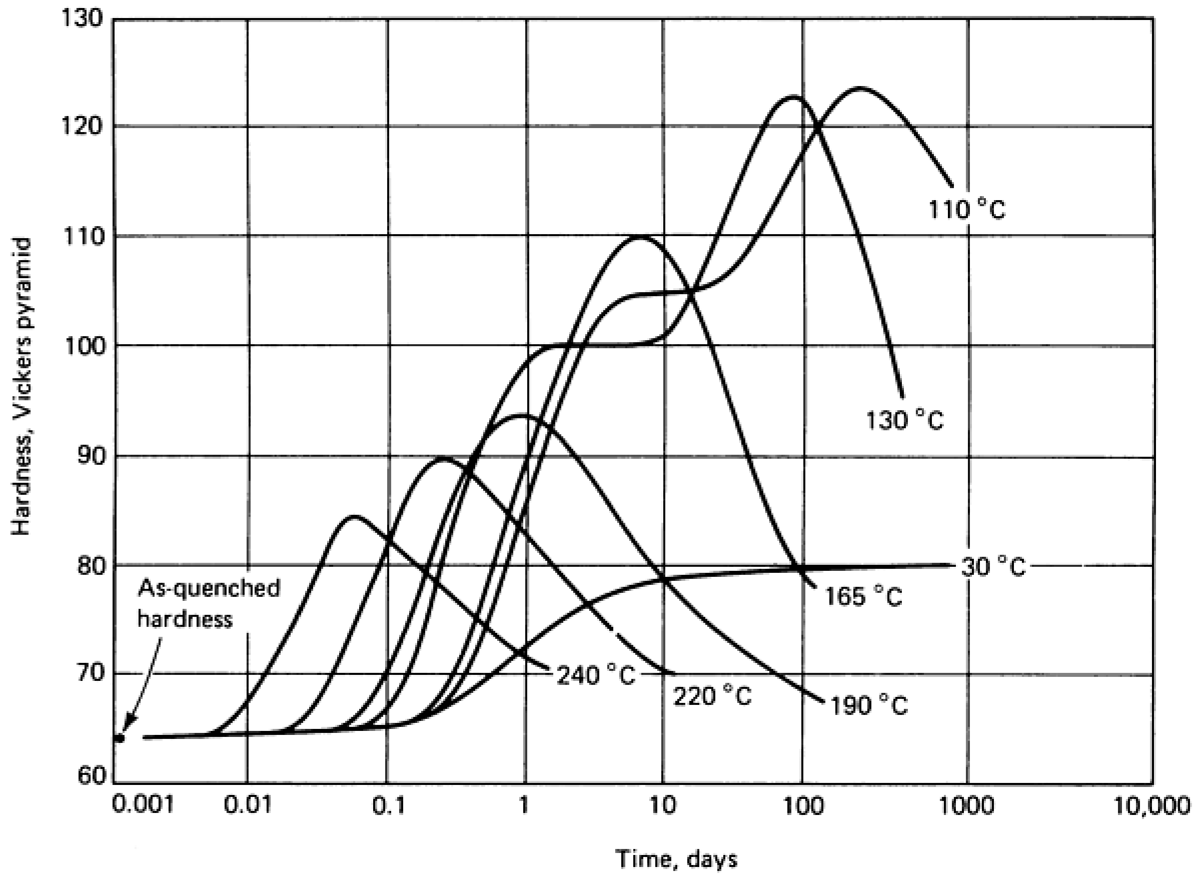

Fig. 30 Hardness as a function of aging time for an Al-4Cu alloy. The alloy was solution annealed for at least 48 h at 520 °C (970 °F), then cooled quickly (water quenched) to 25 °C (77 °F). Adapted from Ref 12

In most commercial precipitation-hardenable alloys, the rate of precipitation is low at ambient temperature, although sufficiently rapid to bring about measurable hardness changes in a reasonable time, as shown in Fig. 30 for aging at 30 °C (85 °F). If hardening occurs at or near ambient temperature, it is termed *age hardening*; aging at other temperatures is called *precipitation hardening.*

Commercial alloys usually contain multiple elements, so that the required heat treating temperatures cannot always be deduced from an examination of related binary-phase diagrams. In many alloys which contain mainly two alloying additions, the ternary phase diagram can be used as a guide for establishing the required heat treatments. For example, consider the aluminum-base alloy 2024. It contains approximately 4% Cu and 1% Mg, with lesser amounts of manganese, silicon, iron, chromium, and zinc. Considering the alloy to be an Al-Cu-Mg ternary alloy, and using 4% Cu and 1% Mg to represent the average concentrations of these elements, then the aluminum-rich end of the ternary phase diagram can be used to illustrate the required heat treatments. This is shown in Fig. 31. The liquidus is about 650 °C (1200 °F), the solidus 570 °C (1060 °F), and the solvus 500 °C (930 °F). Thus, the solution annealing temperature must be between 500 and 570 °C (930 and 1060 °F). When consideration is given to the allowable range of the amounts of copper and magnesium in the 2024 alloy, then the solution annealing range is narrowed. Avoiding heating above the liquidus is of particular importance, because this will allow formation of small regions of liquid in the structure, which on cooling form compounds, and can lead to problems in achieving desired properties. The specification for the solution annealing temperature for alloy 2024 is 488 to 499 °C (910 to 930 °F), only an 11 °C (20 °F) spread. Thus, if 494 °C (921 °F) is used, only a deviation of about ±5 °C (±9 °F) is allowed.

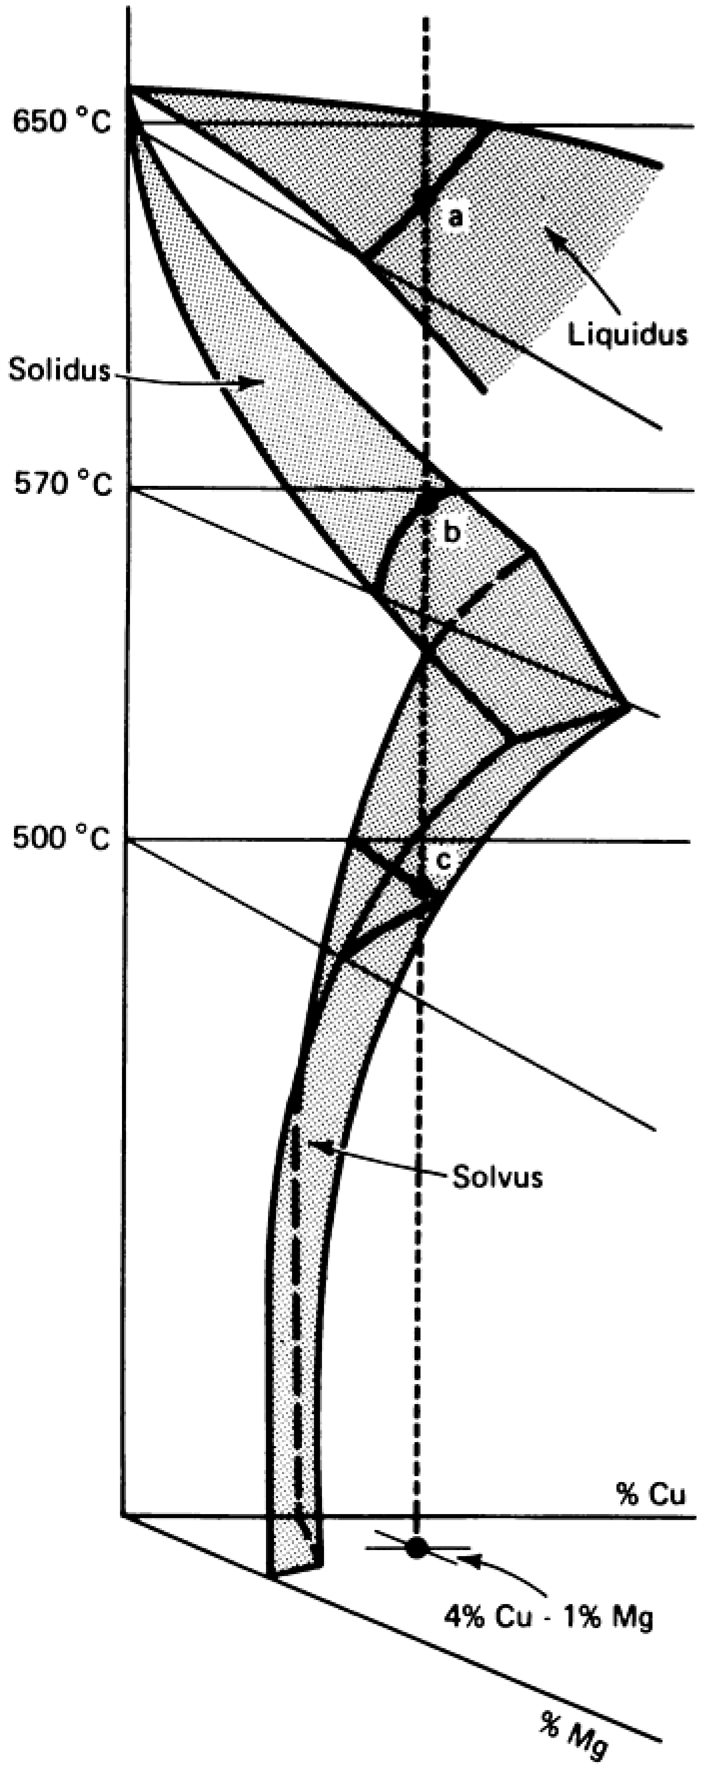

Fig. 31 Schematic illustration of the aluminum-rich end of the Al-Cu-Mg phase diagram, with the liquidus, solidus, and solvus shown for 4Cu-1Mg alloy

Aging of alloy 2024 must be carried out below the solvus, about 500 °C (930 °F). The response to aging for this alloy is typified by the data in Fig. 32. Note that there is a range of combinations of temperature and time which will give about the same optimum mechanical properties.

Development of Two-Phase Structures

In some nonferrous alloys (for example, titanium-base alloys and high-zinc Cu-Zn alloys), the desired structure consists of a mixture of two phases of comparable quantity (unlike the two-phase structures developed in precipitation hardening, where the precipitate is in the minority). The morphology and amount of each are varied by control of the high temperature used and the cooling rate from that temperature. The preferred microstructure can be quite complex, and the required treatment differs considerably for different systems, so that a systematic treatment of the principles involved is difficult. Instead, in this section a specific alloy will be used to illustrate the types of treatments involved.

In the Cu-Zn system, alloys containing about 40% Zn serve as the basis for some commercial alloys (for example, Muntz metal and naval brass). The Cu-Zn phase diagram (Fig. 33) shows that the alloys of interest are in the region of α and β phase stability. The β phase is body-centered cubic, with the copper and zinc atoms located at random on the lattice sites.

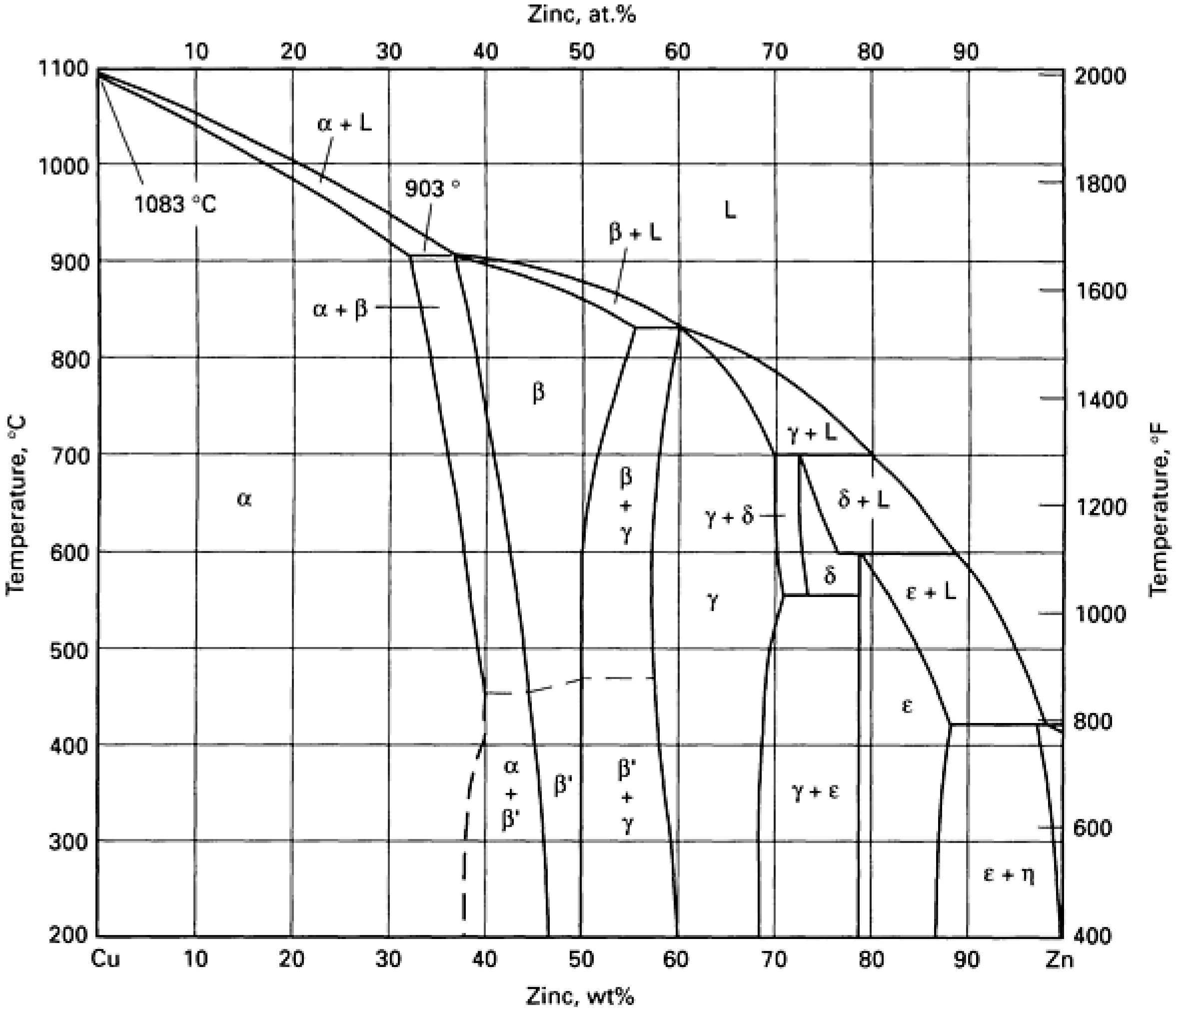

Fig. 33 The Cu-Zn diagram. The β phase is body-centered cubic; the β' phase is an ordered structure based on this arrangement.

On cooling to temperatures below the dashed line (about 450 °C, or 840 °F), the copper and zinc atoms take specific relative positions on the sites, forming an *ordered structure*, or a *superlattice.* This phase is denoted β' in Fig. 33. If the composition is exactly 50 at .% Zn, then the ordered structure is based on a body-centered cubic cell with zinc atoms at the center and copper atoms on the corners (or vice versa).

The formation of an ordered structure from a disordered matrix of the same basic lattice involves the localized exchange of atom positions (via the vacancy mechanism) to the desired structure. This process is depicted schematically in Fig. 34. It can be seen that an ordered region grows by atoms at the β/β' interface, taking on the arrangement of the ordered β' region. When two interfaces from neighboring regions meet, the arrangement of atoms may be out of sequence (out of phase). Such an interface is called an *antiphase boundary*, and the enclosed regions are called *domains.* The properties of the β' ordered structure depend on the degree of perfection (correctness of relative atom location) within the domains and on the domain size, both of which depend on the temperature and time involved in forming β' from β.

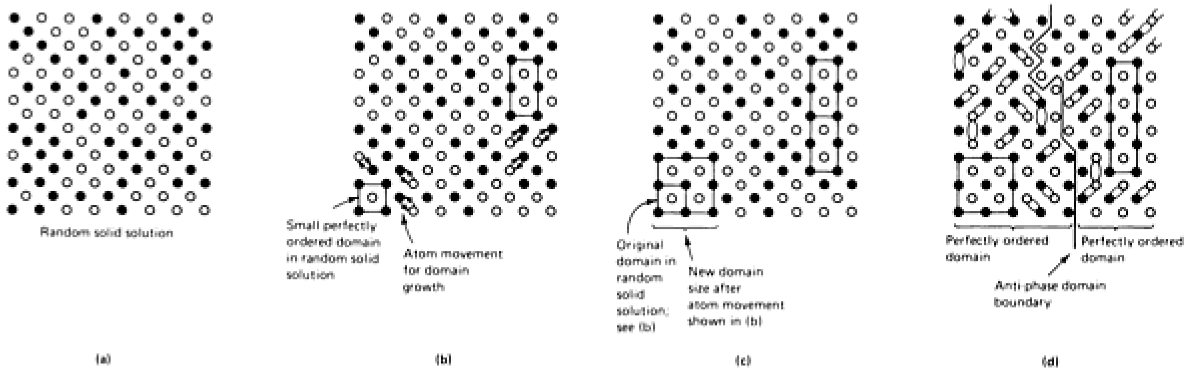

Fig. 34 Schematic illustration of a possible mechanism for the formation of ordered β' from the disordered β in Cu-Zn alloys. Adapted from Ref 5

These alloys in the β' form are not suitable for commercial use, because this structure is brittle. However, alloys in which the β' phase coexists with the ductile α phase are useful. The Cu-40Zn alloy can be heat treated at high temperature so that it is all β. The structure developed at lower temperatures depends on the heat treatment, because this controls precipitation and formation of the α phase. If the alloy is cooled slowly from 800 °C (1470 °F), the phase diagram (Fig. 33) shows that at 25 °C (77 °F) the alloy should consist of approximately equal amounts of α and β'. Figure 35 shows a typical microstructure.

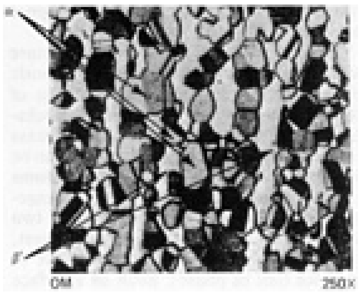

Fig. 35 Typical microstructure of annealed Muntz metal (Cu-40Zn). The clear, white regions are the β', and the dark and gray regions showing annealing twins are α. Optical micrograph. 250×. Adapted from Ref 14

One of the curves in Fig. 36 shows that the amount of β' influences hardness. The alloy was cooled slowly from 700 °C (1290 °F), where it was mostly β, to 25 °C (77 °F), then reheated to temperature for 30 min, followed by rapid cooling. On heating at 800 °C (1470 °F), the structure is all β, and on rapid cooling little α forms. However, the β orders to β', giving a hardness around 90 HB. Reheating for 30 min in the lower temperature range (25 to 500 °C, or 77 to 930 °F) is not sufficient to affect significantly the originally slowly cooled structure, and the hardness remains constant. In this temperature range, the structure consists of approximately equal amounts of α and β'. However, as the temperature increases from 500 °C (930 °F), 30 min is sufficient time to allow the equilibrium amounts and α and β to form. Thus, as the temperature increases, increasing amounts of β and decreasing amounts of α are present at temperature, giving increasing amounts of β' on cooling rapidly to 25 °C (77 °F), and hence a rise in hardness.

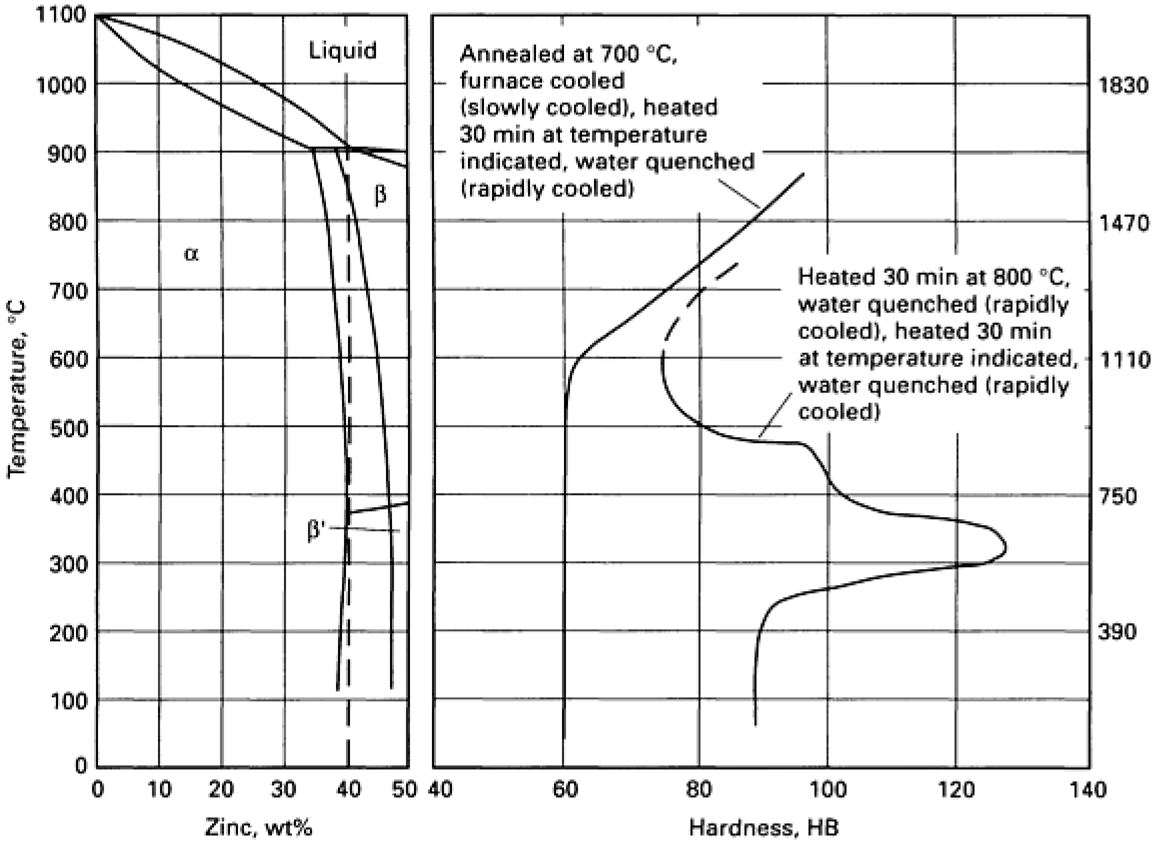

Fig. 36 Influence of heat treatment on the hardness at 25 °C (77 °F) of a Cu-40Zn alloy. Adapted from Ref 15

If the Cu-40Zn alloy is cooled rapidly to 25 °C (77 °F) after sufficient holding (for example, 30 min) above about 750 °C (1380 °F), a structure of essentially all β' is obtained. Often some α is observed to have formed in the β grain boundaries, and the morphology will vary somewhat depending on the exact cooling rate. Usually, the α is present as "needles" emanating from the boundaries, with a clear crystallographic relation between the α and the β' in which it has formed. Figure 37 shows two examples.

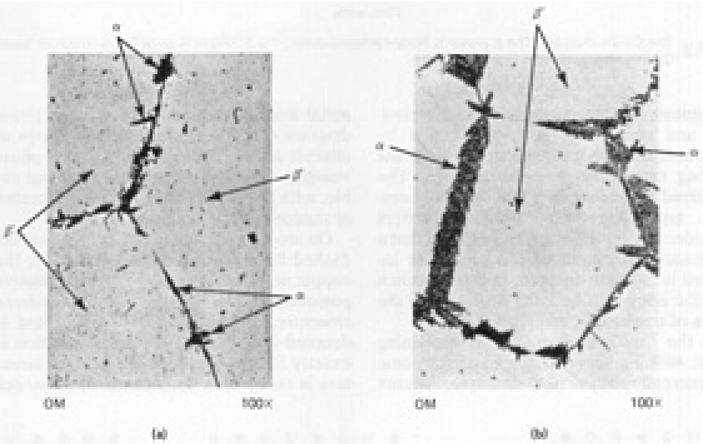

Fig. 37 Microstructures typical of Cu-40Zn alloys cooled rapidly from the β region to 25 °C (77 °F). Even rapid cooling has not prevented some α from forming. (a) Cu-40Zn alloy quenched into ice water from 825 °C (1515 °F). Adapted from Ref 16

On reheating β' in the intermediate temperature range, the morphology of the α formed will vary depending on the exact heat treatment. Also, reheating will influence the change in the ordered structure. Both changes affect properties, and the hardness can be increased considerably by judicious treatment. In Fig. 36 are shown hardness data for a Cu-40Zn alloy after reheating for 30 min following an initial treatment of quenching from 800 °C (1470 °F). Supposedly the maximum hardness obtained by treatment around 300 °C (570 °F) is caused by formation of a fine α precipitate and some changes in the ordered β' phase. The types of microstructures obtained by such heat treatments are illustrated in Fig. 38 for a Cu-42Zn alloy. In this alloy the zinc content is sufficiently high to completely suppress any α formation on rapid cooling from β, giving at 25 °C (77 °F) only β' (Fig. 38a). Reheating for 30 min at 400 °C (750 °F) gives a fine a precipitate on the β' grain boundaries, and a fine inter-crystalline precipitate of α (Fig. 38b). Reheating for 30 min at a higher temperature (600 °C, or 1110 °F) gives a coarser α structure (Fig. 38c).

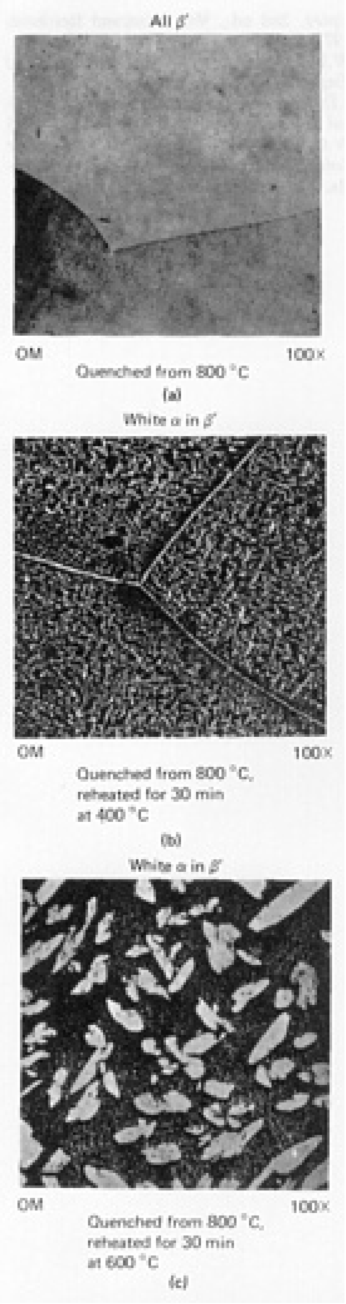

Fig. 38 Microstructures of Cu-42Zn alloy quenched from the β region, then reheated to develop an α precipitate structure. The higher reheating temperature gives a coarser structure and thus a softer material. Adapted from Ref 17

If the rate of cooling from the α region is quite low (several hours to 25 °C, or 77 °F), then α nucleates at a high temperature at which the nucleation rate is low, and the α crystals grow relatively large as few crystals nucleate. This gives a rather coarse structure, typified by Fig. 39(a). As the cooling rate increases, the nucleation rate increases, but the individual α crystals do not have time to grow large before the temperature becomes too low for significant growth to continue. This gives a finer structure (see Fig. 39b) and increases strength. Eventually, the cooling rate becomes sufficient to suppress formation of α altogether, giving a structure entirely of highly unstable β' at 25 °C (77 °F). Figure 40 illustrates the influence of cooling rate from β on hardness.

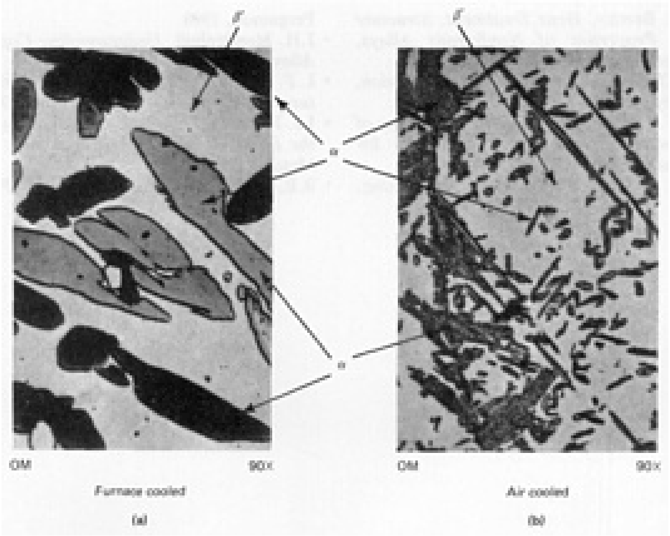

Fig. 39 Microstructures of a Cu-43Zn alloy after cooling from 700 °C (1290 °F), the β region, showing effect of cooling rate on structure of α crystals. Adapted from Ref 18

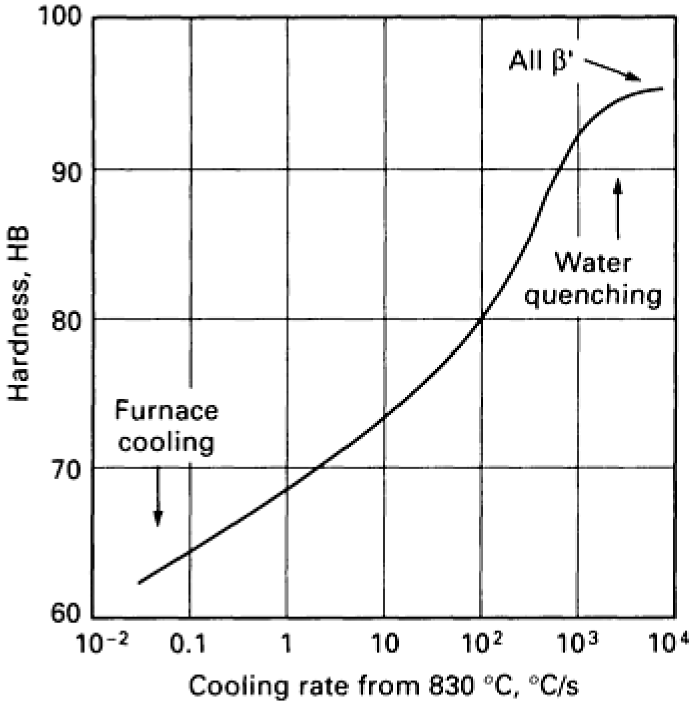

Fig. 40 Effect of cooling rate from the βregion on hardness of a Cu-40Zn alloy. Adapted from Ref 15

Heat Treating of Aluminum Alloys

Introduction

HEAT TREATING in its broadest sense, refers to any of the heating and cooling operations that are performed for the purpose of changing the mechanical properties, the metallurgical structure, or the residual stress state of a metal product. When the term is applied to aluminum alloys, however, its use frequently is restricted to the specific operations employed to increase strength and hardness of the precipitation-hardenable wrought and cast alloys. These usually are referred to as the "heat-treatable" alloys to distinguish them from those alloys in which no significant strengthening can be achieved by heating and cooling. The latter, generally referred to as "non-heat-treatable" alloys, depend primarily on cold work to increase strength. Heating to decrease strength and increase ductility (annealing) is used with alloys of both types; metallurgical reactions may vary with type of alloy and with degree of softening desired. Except for the low-temperature stabilization treatment sometimes given for 5*xxx* series alloys (which is a mill treatment and not discussed in this article), complete or partial annealing treatments are the only ones used for non-heat-treatable alloys. A general overview of these heat treatments is covered in the article "Principles of Heat Treating of Nonferrous Alloys" in this Volume.

Precipitation from Solid Solution

One essential attribute of a precipitation-hardening alloy system is a temperature-dependent equilibrium solid solubility characterized by increasing solubility with increasing temperature (see, for example, the phase diagrams in Fig. 1 and 2). Although this condition is met by most of the binary aluminum alloy systems, many exhibit very little precipitation hardening, and these alloys ordinarily are not considered heat treatable. Alloys of the binary aluminum-silicon and aluminum-manganese systems, for example, exhibit relatively insignificant changes in mechanical properties as a result of heat treatments that produce considerable precipitation. The major aluminum alloy systems with precipitation hardening include:

- Aluminum-copper systems with strengthening from $CuAl_2$
- Aluminum-copper-magnesium systems (magnesium intensifies precipitation)
- Aluminum-magnesium-silicon systems with strengthening from Mg_2Si
- Aluminum-zinc-magnesium systems with strengthening from $MgZn_2$
- Aluminum-zinc-magnesium-copper systems

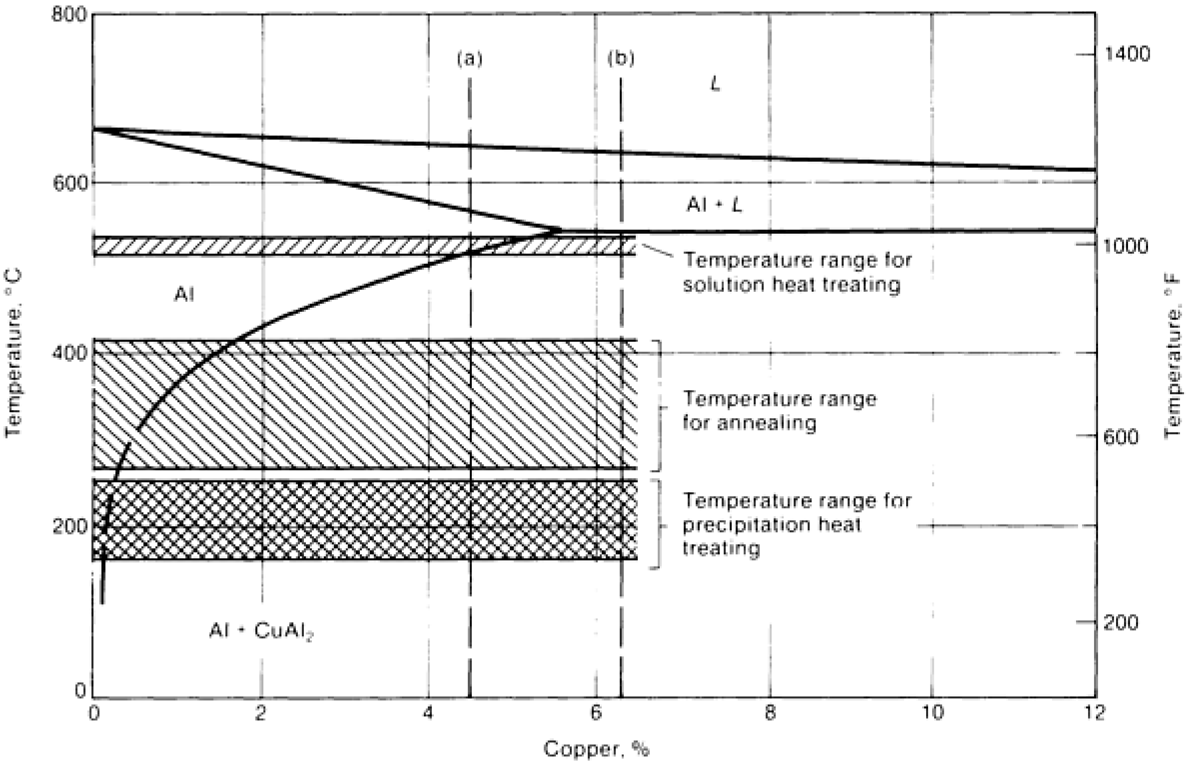

Fig. 1 Portion of aluminum-copper binary phase diagram. Temperature ranges for annealing, precipitation heat treating, and solution heat treating are indicated. The range for solution treating is below the eutectic melting point of 548 °C (1018 °F) at 5.65 wt% Cu.

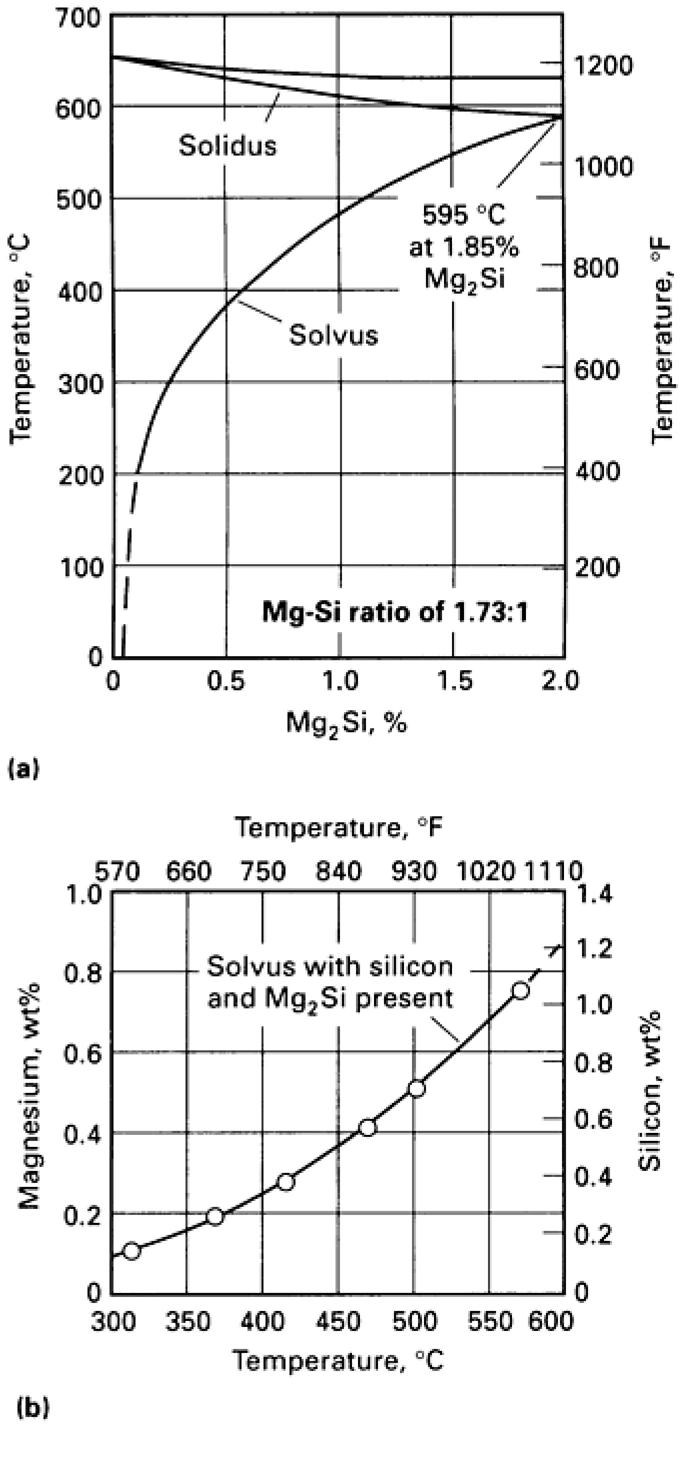

Fig. 2 Equilibrium solubility as function of temperature for (a) Mg_2Si in aluminum with an Mg-Si ratio of 1.73-to-1 and (b) magnesium and silicon in solid aluminum when both Mg_2Si and silicon are present

The general requirement for precipitation strengthening of supersaturated solid solutions involves the formation of finely dispersed precipitates during aging heat treatments (which may include either natural aging or artificial aging). The aging must be accomplished not only below the equilibrium solvus temperature, but below a metastable miscibility gap called the Guinier-Preston (GP) zone solvus line. The supersaturation of vacancies allows diffusion, and thus zone formation, to occur much faster than expected from equilibrium diffusion coefficients. In the precipitation process, the saturated solid solution first develops solute clusters, which then become involved in the formation of transitional (nonequilibrium) precipitates.

The mechanism of strengthening from precipitation involves the formation of coherent clusters of solute atoms (that is, the solute atoms have collected into a cluster but still have the same crystal structure as the solvent phase). This causes a great deal of strain because of mismatch in size between the solvent and solute atoms. Consequently, the presence of the precipitate particles, and even more importantly the strain fields in the matrix surrounding the coherent particles, provide higher strength by obstructing and retarding the movement of dislocations. The characteristic that determines whether a precipitate phase is coherent or noncoherent is the closeness of match or degree of disregistry between atomic spacings on the lattice of the matrix and on that of the precipitate. These changes in properties result from the formation of solute-rich microstructural domains, or GP zones.

The exact size, shape, and distribution of GP zones depend on the alloy in which they form and on the thermal and mechanical history of the specimen. Their shape can sometimes be deduced by refined studies of diffuse x-ray scattering. Under favorable conditions, GP zones can be seen in transmission electron micrographs. Spherical solute-rich zones usually form when the sizes of the solvent and solute atoms are nearly equal, as in the aluminum-silver and aluminum-zinc systems. If there is a large difference in atom sizes, as in the aluminum-copper system, the GP zones usually form as disks whose planes lie parallel with some low-index plane of the matrix lattice. Sometimes, the solute atoms occupy preferred lattice sites within the GP zone, and thus form a small region of lattice order.

The GP zones are of the size range of tens of angstroms in diameter. They are essentially distorted regions of the matrix lattice, rather than discrete particles of a new phase having a different lattice. As such, they are completely coherent with the matrix, imposing local but often large strains on it. These mechanical strains, as well as the presence of a locally solute-rich, sometimes ordered lattice, can account for large changes in mechanical properties of the alloy before any long-range microstructural changes occur.

The GP zones are characteristically metastable and thus dissolve in the presence of a more stable precipitate. This dissolution causes a precipitate-free, visibly denuded region to form around the stable precipitate particles. The final structure consists of equilibrium precipitates, which do not contribute as significantly to hardening. More detailed information about preprecipitation phenomena can be found in the article "Structures Resulting From Precipitation From Solid Solution" in Volume 9 of *ASM Handbook*, formerly 9th Edition *Metals Handbook.*

Precipitation in Aluminum-Copper Alloys. Figure 1, which illustrates the required solubility-temperature relationship needed in precipitation strengthening, shows the temperature ranges required for solution treatment and subsequent precipitate hardening in the aluminum-copper system. The equilibrium solid solubility of copper in aluminum increases as temperature increases--from about 0.20% at 250 °C (480 °F) to a maximum of 5.65% at the eutectic melting temperature of 548 °C (1018 °F). (It is considerably lower than 0.20% at temperatures below 250 °C.) For aluminum-copper alloys containing from 0.2 to 5.6% Cu, two distinct equilibrium solid states are possible. At temperatures above the lower curve in Fig. 1 (solvus), the copper is completely soluble, and when the alloy is held at such temperatures for sufficient time to permit needed diffusion, the copper will be taken completely into solid solution. At temperatures below the solvus, the equilibrium state consists of two solid phases: solid solution, α, plus an intermetallic-compound phase $\theta(Al_2Cu)$. When such an alloy is converted to all solid solution by holding above the solvus temperature and then the temperature is decreased to below the solvus, the solid solution becomes supersaturated and the alloy seeks the equilibrium two-phase condition; the second phase tends to form by solid-state precipitation.

The preceding description is a gross over-simplification of the actual changes that occur under different conditions even in simple binary aluminum-copper alloys. A variety of different nonequilibrium precipitate structures is formed at temperatures below solvus. In alloys of the aluminum-copper system, a succession of precipitates is developed from a rapidly cooled super-saturated solid solution (SSS). These precipitates develop sequentially either with increasing temperature or with increasing time at temperature between room temperature and the solvus. The several stages are identified by the following notation:

$$\text{SSS} \rightarrow \text{GP zones} \rightarrow \theta'' \rightarrow \\ \theta' \rightarrow \theta(Al_2Cu)$$

At temperatures in the natural aging range (about -20 to 60 °C, or 0 to 140 °F), the distribution of copper atoms changes with time from random to the disklike planar aggregates (GP zones), which form on particular crystallographic planes of the aluminum matrix. These aggregates create coherency strain fields that increase resistance to deformation, and their formation is responsible for the changes in mechanical properties that occur during natural aging. At higher temperatures, transition forms of approximate composition Al_2Cu develop and further increase strength. In the highest strength

condition, both the θ" and θ' transition precipitates may be present. When time and temperature are increased sufficiently to form high proportions of the equilibrium θ, the alloy softens and is said to be "overaged."

The commercial heat-treatable aluminum alloys are, with few exceptions, based on ternary or quaternary systems with respect to the solutes involved in developing strength by precipitation. Commercial alloys whose strength and hardness can be significantly increased by heat treatment include 2*xxx*, 6*xxx*, and 7*xxx* series wrought alloys (except 7072) and 2*xx*.0, 3*xx*.0, and 7*xx*.0 series casting alloys. Some of these contain only copper, or copper and silicon, as the primary strengthening alloy addition(s). Most of the heat-treatable alloys, however, contain combinations of magnesium with one or more of the elements copper, silicon, and zinc. Characteristically, even small amounts of magnesium in concert with these elements accelerate and accentuate precipitation hardening, while alloys in the 6*xxx* series contain silicon and magnesium approximately in the proportions required for formulation of magnesium silicide (Mg_2Si). Although not as strong as most 2*xxx* and 7*xxx* alloys, 6*xxx* series alloys have good formability, weldability, machinability, and corrosion resistance, with medium strength.

In the heat-treatable wrought alloys, with some notable exceptions (2024, 2219, and 7178), such solute elements are present in amounts that are within the limits of mutual solid solubility at temperatures below the eutectic temperature (lowest melting temperature). In contrast, some of the casting alloys of the 2*xx*.0 series and all of the 3*xx*.0 series alloys contain amounts of soluble elements that far exceed solid-solubility limits. In these alloys, the phase formed by combination of the excess soluble elements with the aluminum will never be dissolved, although the shapes of the undissolved particles may be changed by partial solution.

Most of the heat-treatable aluminum alloy systems exhibit multistage precipitation and undergo accompanying strength changes analogous to those of the aluminum-copper system. Multiple alloying additions of both major solute elements and supplementary elements employed in commercial alloys are strictly functional and serve with different heat treatments to provide the many different combinations of properties--physical, mechanical, and electrochemical--that are required for different applications. Some alloys, particularly those for foundry production of castings, contain amounts of silicon far in excess of the amount that is soluble or needed for strengthening alone. The function here is chiefly to improve casting soundness and freedom from cracking, but the excess silicon also serves to increase wear resistance, as do other microstructural constituents formed by manganese, nickel, and iron. Parts made of such alloys are commonly used in gasoline and diesel engines (pistons, cylinder blocks, and so forth).

Alloys containing the elements silver, lithium, and germanium are also capable of providing high strength with heat treatment, and in the case of lithium, both increased elastic modulus and lower density, which are highly advantageous--particularly for aerospace applications (see the following section "Aluminum-Lithium Alloys" in this article). Commercial use of alloys containing these elements has been restricted either by cost or by difficulties encountered in producing them. Such alloys are used to some extent, however, and research is being directed toward overcoming their disadvantages.

In the case of alloys having copper as the principal alloying ingredient and no magnesium, strengthening by precipitation can be greatly increased by adding small fractional percentages of tin, cadmium, or indium, or combinations of these elements. Alloys based on these effects have been produced commercially but not in large volumes because of costly special practices and limitations required in processing, and in the case of cadmium, the need for special facilities to avoid health hazards from formation and release of cadmium vapor during alloying. Such alloys, as well as those containing silver, lithium, or other particle-forming elements, may be used on a selective basis in the future.

Aluminum-Lithium Alloys. Like other age-hardened aluminum alloys, aluminum-lithium alloys achieve precipitation strengthening by thermal aging after a solution heat treatment. The precipitate structure is sensitive to a number of processing variables, including, but not limited to, the quenching rate following the solution heat treatment, the degree of cold deformation prior to aging, and the aging time and temperature. Minor alloying elements can also have a significant effect on the aging process by changing the interface energy of the precipitate, by increasing the vacancy concentration, and/or by raising the critical temperature for homogeneous precipitation. Like some other age-hardened 2*xxx* aluminum alloys, aluminum-lithium-base alloys also gain increased strength and toughness from deformation prior to aging. This unusual phenomenon has given rise to a number of thermomechanical processing steps for aluminum-lithium alloys aimed at optimizing mechanical properties after artificial aging.

The age hardening of aluminum-lithium alloys involves the continuous precipitation of δ' (Al_3Li) from a supersaturated solid solution. The aluminum and lithium in the δ' precipitates are positioned at specific locations. The eight shared corner sites are occupied by lithium, and the six shared faces are occupied by aluminum. This gives rise to the aluminum-lithium composition of δ' precipitates. The geometrical similarity between the lattice of the precipitates and the face-centered

cubic lattices of the solid solution facilitates the observed cube/cube orientation. The lattice parameters of the precipitate are also closely matched to those of the matrix. Consequently, the microstructure of an aluminum-lithium alloy solution heat treated and aged for short times below the δ' solvus is characterized by a homogeneous distribution of coherent, spherical δ' precipitates.

Aluminum-lithium-base alloys are microstructurally unique. They differ from most of the aluminum alloys in that once the major strengthening precipitate (δ') is homogeneously precipitated, it remains coherent even after extensive aging. In addition, extensive aging at high temperatures (>190 °C, or 375 °F) can result in the precipitation of icosahedral grain-boundary precipitates with five-fold symmetry. Although the quasi-crystalline structure and the composition of these grain-boundary precipitates are not yet exactly known, it has been suggested that both the precipitates and the precipitate-free zones (PFZs) near the grain boundaries might play a major role in the fracture process.

The low ductility and toughness of binary aluminum-lithium alloys can be traced, at least in part, to the inhomogeneous nature of their slip, resulting from coherent-particle hardening of spherical δ' precipitates. The presence of equilibrium δ(aluminum-lithium) precipitates at grain boundaries can also cause PFZs, which can induce further strain localization and promote intergranular failure. Consequently, for the development of commercial alloys, slip has been homogenized by introducing dispersoids (manganese, zirconium) and semicoherent/incoherent precipitates, such as T_1 (Al_2CuLi), θ' (Al_2Cu), or S (Al_2LiMg), through copper or magnesium additions. Magnesium and copper improve the strength of aluminum-lithium alloys through solid-solution and precipitate strengthening, and they can minimize the formation of PFZs near grain boundaries. Zirconium, which forms the cubic Al_3Zr coherent dispersoid, stabilizes the subgrain structure and suppresses recrystallization.

Development of commercially available aluminum-lithium-base alloys was started by adding lithium to aluminum-copper, aluminum-magnesium, and aluminum-copper-magnesium alloys. These alloys were chosen to superimpose the precipitation-hardening characteristics of aluminum-copper-, aluminum-copper-magnesium-, and aluminum-magnesium-base precipitates to the hardening of lithium-containing precipitates. Proceeding in this manner, alloys 2020 (Al-Cu-Li-Cd), 01429 (Al-Mg-Li), 2090 (Al-Cu-Li), and 2091 and 8090 (Al-Cu-Mg-Li) evolved. Besides these registered alloys, other commercial aluminum-lithium alloys include Weldalite 049 and CP276. Properties and applications of these alloys are discussed in the article "Aluminum-Lithium Alloys" in ***Properties and Selection: Nonferrous Alloys and Special-Purpose Materials,*** Volume 2 of *ASM Handbook*, formerly 10th Edition *Metals Handbook.*

In terms of δ' precipitation, the only effect of magnesium appears to be a reduction in the solubility of lithium. The microstructure of an aluminum-magnesium-lithium alloy in the early stages of aging is similar to that of an aluminum-lithium alloy. Precipitation in the aluminum-copper-lithium system is more complicated than that in either the aluminum-lithium or aluminum-magnesium-lithium systems.

Effects on Physical and Electrochemical Properties. The above description of the precipitation processes in commercial heat-treatable aluminum alloys (as well as the heat-treatable binary alloys, none of which is used commercially in wrought form) affect not only mechanical properties but also physical properties (density and electrical and thermal conductivities) and electrochemical properties (solution potential). On the microstructural and submicroscopic scales, the electrochemical properties develop point-to-point nonuniformities that account for changes in corrosion resistance.

Measurements of changes in physical and electrochemical properties have played an important role in completely describing precipitation reactions and are very useful in analyzing or diagnosing whether heat-treatable products have been properly or improperly heat treated. Although they may be indicative of the strength levels of products, they cannot be relied upon to determine whether or not the product meets specified mechanical-property limits. Since elements in solid solution are always more harmful to electrical conductivity than the same elements combined with others as intermetallic compounds, thermal treatments are applied to ingots used for fabrication of electrical conductor parts. These thermal treatments are intended to precipitate as much as possible of the dissolved impurities. Iron is the principal element involved, and although the amount precipitated is only a few hundredths of a percent, the effect on electrical conductivity of the wire, cable, or other product made from the ingot is of considerable practical importance. These alloys may or may not be heat treatable with respect to mechanical properties. Electrical conductor alloys 6101 and 6201 are heat treatable. These alloys are used in tempers in which their strengthening precipitate, the transition form of Mg_2Si, is largely out of solid solution to optimize both strength and conductivity.

Heat Treating of Aluminum Alloys

Strengthening by Heat Treatment

Heat treatment to increase strength of aluminum alloys is a three-step process:

- Solution heat treatment: dissolution of soluble phases
- Quenching: development of supersaturation
- Age hardening: precipitation of solute atoms either at room temperature (natural aging) or elevated temperature (artificial aging or precipitation heat treatment)

Each of these steps and the use of quench-factor analysis are described in the following four sections. Typical solution and precipitation heat treatments for mill products are given in Tables 1(a), 1(b), 1(c) and Table 2, and treatments for castings are given in Table 3. Temper designations are defined at the end of this article.

Table 1(a) Typical solution and precipitation heat treatments for commercial heat-treatable aluminum alloy mill products with copper alloying

(a) Material should be quenched from the solution-treating temperature as rapidly as possible and with minimum delay after removal from the furnace. When material is quenched by total immersion in water, unless otherwise indicated, the water should be at room temperature, and should be suitably cooled so that it remains below 38 °C (100 °F) during the quenching cycle. Use of high-velocity, high-volume jets of cold water also is effective for some materials.

(b) The nominal temperatures listed should be attained as rapidly as possible and maintained within ±6 °C (± 10 °F) of nominal during the time at temperature.

(c) Approximate time at temperature. The specific time will depend on the time required for the load to reach temperature. The times shown are based on rapid heating, with soak time measured from the time the load reaches a temperature within 6 °C (10 °F) of the applicable temperature.

(d) Cold working subsequent to solution heat treatment and prior to any precipitation heat treatment is necessary to attain the specified properties for this temper.

(e) Stress relieved by stretching to produce a specified amount of permanent set subsequent to solution heat treatment and prior to any precipitation heat treatment.

(f) Stress relieved by 1 to 5% cold reduction after solution treatment and prior to precipitation heat treatment.

(g) Quenched in water at 100 °C (212 °F).

(h) These heat treatments also apply to alclad sheet and plate of these alloys.

(i) Quenched with room-temperature air blast.

(j) See U.S. Patent 4,840,852.

(k) An alternative heat treatment of 8 h at 177 °C (350 °F) may also be used.

(l) Quenched in water at 60 to 80 °C (140 to 180 °F).

(a) Material should be quenched from the solution-treating temperature as rapidly as possible and with minimum delay after removal from the furnace. When material is quenched by total immersion in water, unless otherwise indicated, the water should be at room temperature, and should be suitably cooled so that it remains below 38 °C (100 °F) during the quenching cycle. Use of high-velocity, high-volume jets of cold water also is effective for some materials.

(b) The nominal temperatures listed should be attained as rapidly as possible and maintained within ±6 °C (±10 °F) of nominal during the time at temperature.

(c) Approximate time at temperature. The specific time will depend on the time required for the load to reach temperature. The times shown are based on rapid heating, with soak time measured from the time the load reaches a temperature within 6 °C (10 °F) of the applicable temperature.

(d) By suitable control of extrusion temperature, product may be quenched directly from extrusion press to provide specified properties for this temper. Some products may be adequately quenched in room-temperature air blast.

(e) Alternate heat treatments of 4 h at 190 °C (375 °F) or 8 h at 175 °C (350 °F) may also be used. See U.S. Patent 4,082,578.

(f) These heat treatments also apply to alclad sheet and plate in these alloys.

(g) Applicable to tread plate only.

(h) Stress relieved by stretching to produce a specified amount of permanent set prior to precipitation heat treatment.

(i) An alternative heat treatment of 8 h at 170 °C (340 °F) also may be used.

(j) Cold working after solution treatment is necessary to attain specified properties during precipitation heat treatments.

(k) Cold working after precipitation heat treatment is necessary to attain specified properties.

(l) Stress relieved by 1 to 5% cold reduction subsequent to solution heat treatment and prior to precipitation heat treatment.

(m) An alternative treatment of 3 h at 182 °C (360 °F) also may be used.

(n) An alternative treatment of 6 h at 182 °C (360 °F) also may be used.

(o) See U.S. Patent 4,589,932.

(p) Two weeks of natural aging to a T4 condition.

(q) Artificially aged in laboratory from T4 to T6.

(a) Material should be quenched from the solution-treating temperature as rapidly as possible and with minimum delay after removal from the furnace. When material is quenched by total immersion in water, unless otherwise indicated, the water should be at room temperature, and should be suitably cooled so that it remains below 38 °C (100 °F) during the quenching cycle. Use of high-velocity, high-volume jets of cold water also is effective for some materials.

(b) The nominal temperatures listed should be attained as rapidly as possible and maintained within ±6 °C (±10 °F) of nominal during the time at temperature.

(c) Approximate time at temperature. The specific time will depend on the time required for the load to reach temperature. The times shown are based on rapid heating, with soak time measured from the time the load reaches a temperature within 6 °C (10 °F) of the applicable temperature.

(d) Stress relieved by stretching to produce a specified amount of permanent set after solution treatment and prior to precipitation heat treatment.

(e) No solution heat treatment; 72 h at room temperature following press quench followed by two-stage precipitation heat treatment comprised of 8 h at 107 °C (225 °F) plus 16 h at 149 °C (300 °F).

(f) Aging practice varies with product, size, nature of equipment, loading procedures, and furnace-control capabilities. The optimum practice for a specific item can be ascertained only by actual trial treatment of the item under specific conditions. Typical procedures involve a two-stage treatment comprised of 3 to 30 h at 121 °C (250 °F) followed by 15 to 18 h at 163 °C (325 °F) for extrusions. An alternative two-stage treatment of 8 h at 99 °C (210 °F) followed by 24 to 28 h at 163 °C (325 °F) also may be used.

(g) Aging of aluminum alloys 7050, 7075, 7175, and 7475 from any temper to the T73 or T76 temper series requires closer-than-normal controls on aging variables such as time, temperature, heatup rate, and so forth, for any given item. In addition, when material in a T6-type temper is reaged to a T73- or T76-type temper, the specific condition of the T6 material (such as property levels and other effects of processing variables) is extremely important and will affect the capability of the reaged material to conform to the requirements specified for the applicable T73- or T76-type temper.

(h) Two-stage treatment comprised of 6 to 8 h at 107 °C (225 °F) followed by: 24 to 30 h at 163 °C (325 °F) for sheet and plate; 8 to 10 h at 177 °C (350 °F) for rolled or cold finished rod and bar; 6 to 8 h at 177 °C (350 °F) for extrusions and tube; 8 to 10 h at 177 °C (350 °F) for forgings in the T73 temper; and 6 to 8 h at 177 °C (350 °F) for forgings in the T7352 temper.

(i) These heat treatments also apply to alclad sheet and plate of these alloys.

(j) An alternative two-stage treatment comprised of 4 h at 96 °C (205 °F) followed by 8 h at 157 °C (315 °F) also may be used.

(k) For sheet, plate, tube, and extrusions, an alternative two-stage treatment comprised for 6 to 8 h at 107 °C (225 °F) followed by 14 to 18 h at 168 °C (335 °F) may be used, provided that a heatup rate of approximately 14 °C/h (25 °F/h) is employed. For rolled or cold finished rod and bar, the alternative treatment is 10 h at 177 °C (350 °F).

(l) An alternative three-stage treatment comprised of 5 h at 99 °C (210 °F), 4 h at 121 °C (250 °F), and then 4 h at 149 °C (300 °F) may also be used.

(m) Quenched in water at 60 to 80 °C (140 to 180 °F).

(n) Stress relieved by 1 to 5% cold reduction after solution treatment and prior to precipitation heat treatments.

(o) 7175-T74 and -T7452 heat treatments are directed to specific results, may vary from supplier to supplier and are either proprietary or patented.

(p) Must be preceded by soak at 466 to 477 °C (870 to 890 °F). See U.S. Patent 3,791,880.

Table 2 Soak times and maximum quench delays for solution treatment of wrought aluminum alloys

(a) S, sand; P, permanent mold.

(b) Unless otherwise indicated, solution treating is followed by quenching in water at 65-100 °C (150-212 °F).

(c) Except where ranges are given, listed temperatures are ±6 °C or ±10 °F.

(d) Casting wall thickness, solidification rate, and grain refinement affect the solution heat-treatment cycle in alloys 201.0, 204.0, and 206.0, and care must be taken in approaching the final solution temperature. Too rapid an approach can result in the occurrence of incipient melting.

(e) For castings with thick or other slowly solidified sections, a pre-solution heat treatment ranging from about 490 to 515 °C (910 to 960 °F) may be needed to avoid too rapid a temperature rise to the solution temperature and the melting of $CuAl_2$.

(f) Temper T43 for 201.0 was developed for improved impact resistance with some decrease in other mechanical properties. Typical Charpy value is 20 J (15 ft · lb).

(g) The French precipitation treatment technology for the heat treatment of 204.0 alloy requires 12 h at temperature. The aging temperatures of 140, 160, or 180 °C (285, 320, or 355 °F) are selected to meet the required combination of properties.

(h) Stress relieve for dimensional stability as follows: hold 5 h at 413 ± 14 °C (775 ± 25 °F); furnace cool to 345 °C (650 °F) over a period of 2 h or more; furnace cool to 230 °C (450 °F) over a period of not more than $\frac{1}{2}$ h; furnace cool to 120 °C (250 °F) over a period of approximately 2 h; cool to room temperature in still air outside the furnace.

(i) No quench required; cool in still air outside the furnace.

(j) Air-blast quench from solution-treating temperature.

(k) Casting process varies (sand, permanent mold, or composite) depending on desired mechanical properties.

(l) Solution heat treat as indicated, then artificially age by heating uniformly at the temperature and for the time necessary to develop the desired mechanical properties.

(m) Quench in water at 65-100 °C (150-212 °F) for 10-20 s only.

(n) Cool to room temperature in still air outside the furnace.

Solution Heat Treating

To take advantage of the precipitation-hardening reaction, it is necessary first to produce a solid solution. The process by which this is accomplished is called solution heat treating, and its objective is to take into solid solution the maximum practical amounts of the soluble hardening elements in the alloy. The process consists of soaking the alloy at a temperature sufficiently high and for a time long enough to achieve a nearly homogeneous solid solution.

Nominal commercial solution heat-treating temperature is determined by the composition limits of the alloy and an allowance for unintentional temperature variations. Although ranges normally listed allow variations of ±6 °C (±10 °F) from the nominal, some highly alloyed, controlled-toughness, high-strength alloys require that temperature be controlled within more restrictive limits. Broader ranges may be allowable for alloys with greater intervals of temperature between their solvus and eutectic melting temperatures.

Overheating. Care must be exercised to avoid exceeding the initial eutectic melting temperature. If appreciable eutectic melting occurs as a result of overheating, properties such as tensile strength, ductility, and fracture toughness may be degraded. Materials that exhibit microstructural evidence of overheating are generally categorized as unacceptable by specification. Evidence of grain-boundary melting that occurs above the eutectic melting temperature of the alloy usually is not detectable by either visual examination or nondestructive testing.

Although maximum temperature must be restricted to avoid melting, the lower limit should, when possible, be above the temperature at which complete solution occurs (solvus). In the alloy represented by line (a) in Fig. 1, these temperatures would be about 575 and 515 °C (1065 and 960 °F), respectively. However, under production conditions, the temperature interval for solution treatment (shown in Fig. 1 for typical 2*xxx* or 2*xx.x*) alloys provides a margin to safeguard against eutectic melting and a cushion on the low side for increased solution and diffusion rates.

For alloys containing more than 5.65% Cu, complete solution can never occur. For these alloys, such as alloy 2219 (which has 5.8 to 6.8% Cu), the minimum solution heat-treating temperature is established so that it is as close as practical to the eutectic temperature while providing a margin of safety commensurate with the capability of the equipment. Line (b) in Fig. 1 is another example of a composition above 5.65% Cu that does not allow complete dissolution of aluminum-copper precipitates.

For more complex ternary and quaternary systems, solution treatments are modified according to the effect of new elements on the solid solubility and/or the eutectic melting points of the basic binary system. In aluminum-lithium alloys, for example, magnesium reduces the solubility of lithium in aluminum. In the aluminum-copper system, magnesium also lowers the eutectic melting point. The proximity of typical solution-treating temperature ranges to eutectic melting temperatures for three common aluminum-copper-magnesium alloys is shown in the following table:

Alloy	**Solution-treating temperature**		Eutectic melting temperature	
	°C	**°F**	**°C**	°F
2014	496-507	925-945	510	**950**
2017	496-507	925-945	513	**955**

Similar considerations apply to other age-hardenable alloy systems such as aluminum-magnesium-silicon alloys. For example, according to Fig. 2(a), a 1.08% Mg_2Si alloy would be soaked at a temperature in excess of 500 °C (930 °F) but below the solidus of 595 °C (1100 °F) to avoid incipient melting. However, because some alloy constituents may form complex eutectics that melt at temperatures below the equilibrium eutectic temperature, the upper limit for solution treatment of aluminum-magnesium-silicon alloys is in the range of 515 to 540 °C (960 to 1000 °F). At 540 °C (1000 °F), about 0.6% Mg can be placed in solution (Fig. 2b).

Nonequilibrium Melting. When high heating rates are employed, the phenomenon of nonequilibrium melting must be considered. This phenomenon can also be explained with the help of the aluminum-copper phase diagram (Fig. 1). The room-temperature microstructure of an F-temper product containing 4% Cu consists of a solid solution of copper in aluminum and particles of Al_2Cu. When this product is heated slowly, the Al_2Cu begins to dissolve, and if heating is slow enough, all of the Al_2Cu is dissolved when temperatures above the solvus (500 °C, or 932 °F) are reached. When the heating rate is high, however, much of the Al_2Cu remains undissolved. If a material with this microstructure is heated at or above the eutectic temperature of 548 °C (1018 °F), melting will begin at the interface between the Al_2Cu and the matrix. With sufficient time above the eutectic temperature, this metastable liquid will dissolve to form a solid solution and will leave no trace provided that hydrogen gas has not condensed at the interface to form a void. If the product is quenched before the liquid has time to equilibrate, however, it will solidify and form fine eutectic rosettes. This nonequilibrium melting should not be confused with true equilibrium melting, which would occur in any alloy containing more than 5.65% Cu. In such an alloy, eutectic melting is equilibrium melting. No matter how long such an alloy is held above the eutectic temperature, the liquid will never solidify. In commercial alloys, which usually are ternaries or quaternaries of the major alloying elements, the situation is more complex. Different phases have different solvus temperatures, and non-equilibrium melting may occur at different temperatures depending on composition, size of precipitates, and rate of heating. When new solution heat-treating equipment (which provides higher heating rates) is employed, careful examination of alloy microstructures should be included as part of the certification process.

Underheating. When the temperatures attained by the parts or pieces being heat treated are appreciably below the normal range, solution is incomplete, and strength somewhat lower than normal is expected. In the aluminum-copper

system (Fig. 1), the shallow slope of the solvus at its intersection with the composition line indicates that a slight decrease in temperature will result in a large reduction in the concentration of the solid solution and a correspondingly significant decrease in final strength. The effect of solution-treating temperature on the strength of two aluminum alloys is illustrated by the following data:

Solution-treating temperature		**Tensile strength**		Yield strength	
°C	**°F**	**MPa**	**ksi**	**MPa**	ksi
6061-T6 sheet 1.6 mm (0.064 in.) thick					
493	920	301	43.7	272	**39.4**
504	940	316	45.8	288	**41.7**
516	960	333	48.3	305	**44.3**
527	980	348	50.5	315	**45.7**
2024-T4 sheet 0.8 mm (0.032 in.) thick					
488	910	419	60.8	255	**37.0**
491	915	422	61.2	259	**37.5**
493	920	433	62.8	269	**39.0**
496	**925**	**441**	**63.9**	**271**	39.3

In the tabulation above, note especially the effects of small increments of temperature, within the normal range, on the properties of 0.8 mm (0.032 in.) 2024-T4 sheet.

Solution-Treating Time. The time at the nominal solution heat-treating temperature (soak time) required to effect a satisfactory degree of solution of the undissolved or precipitated soluble phase constituents and to achieve good homogeneity of the solid solution is a function of microstructure before heat treatment. This time requirement can vary from less than a minute for thin sheet to as much as 20 h for large sand or plaster-mold castings. Guideline information for soak times required for wrought products of various section thicknesses is given in Table 2. Similar guidelines for castings are presented in Table 3. The time required to heat a load to the treatment temperature in furnace heat treatment also increases with section thickness and furnace loading, and thus total cycle time increases with these factors.

Soak time for alclad sheet and for parts made from alclad sheet must be held to a minimum, because excessive diffusion of alloying elements from the core into the cladding reduces corrosion protection. For the same reason, reheat treatment

of alclad sheet less than 0.75 mm (0.030 in.) thick generally is prohibited, and the number of reheat treatments permitted for thicker alclad sheet is limited.

The soak times for wrought alloys take into account the normal thermal lag between furnace and part and the difference between surface and center temperatures for commercial equipment qualified to the standards of MIL-H-6088. The rapid heating rates of salt baths permit all immersion time to be counted as soak time unless the bath temperature drops below the minimum of the range. Even then, soak time begins as soon as the bath temperature returns to the minimum. In air furnaces, soak time does not begin until all furnace instruments return to their original set temperature--that is, the temperature reading before insertion of the load.

In air furnaces, thermocouples may also be attracted to, or buried in, parts located in the load in such a manner as to represent the hottest and coldest temperatures in each zone. In this way, it is possible to ensure that adequate soaking is obtained.

Special consideration is given also to establishing soak times for hand and die forgings; soak time in some specifications is extended to complete solution and homogenization in areas that received marginal reduction during forging. Considerable variation exists in the amount of soak time added; some specifications call for an arbitrary addition, such as one hour, and others require one hour per inch of thickness of the original forging.

In air furnaces, careful attention should be given to arrangement of the load. Air how and natural temperature distribution within the furnace should be arranged to:

- Offer minimum resistance to air flow
- Produce the least disturbance in the natural temperature distribution
- Afford constant replenishment of the envelope of air around each part

It is common practice to specify a minimum spacing of 50 mm (2 in.) between parts, but large complex shapes may require considerably greater spacing. Many operators have found conservative loading practices to be more economical in the long run than heavier loading, because with lighter loads heating rates are higher and fewer rejections and service failures are encountered.

High-Temperature Oxidation. There is a condition, commonly but erroneously known as HTO or high-temperature oxidation, which can lead to deterioration of properties in aluminum alloys. High-temperature oxidation is a misnamed condition of hydrogen diffusion that affects surface layers during elevated-temperature treatment. This condition can result from moisture contamination in the furnace atmosphere and is sometimes aggravated by sulfur (as in heat-treatment furnaces also used for magnesium alloy castings) or other furnace refractory contamination.

Moisture in contact with aluminum at high temperatures serves as a source of nascent hydrogen, which diffuses into the metal. Foreign materials, such as sulfur compounds, function as decomposers of the natural oxide surface film, eliminating it as a barrier either between the moisture and the aluminum or between the nascent hydrogen and the aluminum. The most common manifestation of high-temperature oxidation is surface blistering, but occasionally the only manifestations are internal discontinuities or voids, which can be detected only by careful ultrasonic inspection or by metallographic techniques.

It is important to recognize that the symptoms of high-temperature oxidation are identical to those of unsoundness or high gas content in the original ingot or of other improper mill practice. Blisters resulting from ingot defects, improper extrusion or improper rolling may be lined up in the direction of working. However, it usually is impossible to distinguish among defect sources, and therefore the possibility that a contaminated atmosphere is the cause of the defects must be checked.

Not all alloys and product forms are equally vulnerable to this type of attack. The 7*xxx* series alloys are most susceptible, followed by the 2*xxx* alloys. Extrusions undoubtedly are the most susceptible form; forgings are probably second. Low-strength alloys and alclad sheet and plate are relatively immune to high-temperature oxidation. (Blistering of alclad material as a result of inadequate bonding is not the same as the blistering caused by high-temperature oxidation.)

If the protective oxide film formed during mill operations is removed from the mill product by a subsequent mechanical conditioning operation such as sanding, the conditioned surface will be more susceptible to high-temperature oxidation than those from which the film was not removed.

Moisture can be minimized by thoroughly drying parts and racks before they are charged. Drain holes often are needed in racks of tubular construction to avoid entrapment of water. Another common requirement is adjustment of the position of the quench tank with respect to furnace doors and air intake. Because it is unlikely that all moisture can be eliminated from the atmosphere in a production heat-treating furnace, it is extremely important to eliminate all traces of other contaminants from both the parts and the furnace atmosphere.

The most virulent contaminants in attacking aluminum are sulfur compounds. Residues from forming or machining lubricants, or from a sulfur dioxide protective atmosphere used in prior heat treatment of magnesium, are potential sources of sulfur contamination. In one plant, surface contamination resulted from sulfur-containing materials in tote boxes used to transport parts. In another, an epidemic of blistering was cured by rectifying a "sour" degreaser. In a third instance, it was found that a vapor-degreasing operation was not completely removing a thin, hard waxy residue, and an alkaline cleaning operation was added.

Very often, the source of contamination is obscure and difficult to detect, and the problem must be combated in another way. The most common of the alternative methods is use of a protective fluoborate compound in the furnace. Such a compound usually is effective in minimizing the harmful effects of moisture and other undesirable contaminants because it forms a barrier layer or film on the aluminum surface. The additive is not a universal solution; in some applications, high-temperature oxidation has occurred even though a fluoborate compound was employed. Also, the use of such compounds, particularly ammonium fluoborate, may present a hazard to personnel if used in poorly sealed furnaces or in furnaces that discharge their atmospheres into enclosed areas.

Protective fluoborate compounds accentuate staining or darkening of the parts being treated. (At times, this attack, particularly on parts located near the protective-compound container during heat treatment, has been severe enough to be termed "corrosion.") Although this minor nuisance might be considered a small price to pay for solution of a problem of high-temperature oxidation, the residual compound in the furnace dissipates slowly. Therefore, subsequent loads of alloys and product forms whose end uses require bright surfaces, and that are not susceptible to high-temperature oxidation, may be detrimentally affected.

Successful use of fluoborate protective compounds appears to depend on specifying the right amount for each furnace; this must be established on a trial-and-error basis. One aircraft manufacturer adds 4 g/m^3 (0.004 oz/ft^3) of furnace chamber to each load. Another adds 0.45 kg (1 lb) per shift to a metal container hung on the furnace chamber wall, thus avoiding loss of the compound during quenching.

A second method of combating high-temperature oxidation is to anodize the work before it is heat treated. The resultant aluminum oxide film prevents attack by contaminants in the furnace atmosphere. The only deterrents to the use of anodizing are its cost (in money and time) and the slight surface frostiness which results from the subsequent stripping operation.

The usual objection to the blistered surface produced by high-temperature oxidation is its unsightly appearance. This often can be improved (for salvage purposes) by applying local pressure to flatten each blister and then finishing by a mechanical process such as polishing, buffing, sanding, or abrasive blasting. In general, the effect of HTO on static properties and fatigue strength is slight. However, if a void resulting from HTO is located close to another stress concentration, such as a hole, much greater degradation of fatigue strength is likely. In critical aluminum alloy forgings, any blistering must be evaluated carefully for its effect on the integrity of the part. Any "cosmetic" salvage should be performed only after it has been established that the blisters are superficial and will not remain in the finished product.

Precipitation Heat Treating without Prior Solution Heat Treatment. Certain alloys that are relatively insensitive to cooling rate during quenching can be either air cooled or water quenched directly from a final hot-working operation. In either condition, these alloys respond strongly to precipitation heat treatment. This practice is widely used in producing thin extruded shapes of alloys 6061, 6063, 6463, and 7005. Upon precipitation heat treating after quenching at the extrusion press, these alloys develop strengths nearly equal to those obtained by adding a separate solution heat treating operation. Changes in properties occurring during the precipitation treatment follow the principles outlined in the discussion of solution heat-treated alloys.

Quenching

Quenching is in many ways the most critical step in the sequence of heat-treating operations. The objective of quenching is to preserve the solid solution formed at the solution heat-treating temperature, by rapidly cooling to some lower temperature, usually near room temperature. From the preceding general discussion, this statement applies not only to retaining solute atoms in solution, but also to maintaining a certain minimum number of vacant lattice sites to assist in promoting the low-temperature diffusion required for zone formation. The solute atoms that precipitate either on grain boundaries, dispersoids, or other particles, as well as the vacancies that migrate (with extreme rapidity) to disordered regions, are irretrievably lost for practical purposes and fail to contribute to the subsequent strengthening.

In most instances, to avoid those types of precipitation that are detrimental to mechanical properties or to corrosion resistance, the solid solution formed during solution heat treatment must be quenched rapidly enough (and without interruption) to produce a supersaturated solution at room temperature--the optimum condition for precipitation hardening. The resistance to stress-corrosion cracking of certain copper-free aluminum-zinc-magnesium alloys, however, is improved by slow quenching. Most frequently, parts are quenched by immersion in cold water or, in continuous heat treating of sheet, plate, or extrusions in primary fabricating mills, by progressive flooding or high-velocity spraying with cold water. However, parts of complex shape, often with both thin and thick sections (such as die forgings, most castings, impact extrusions, and components formed from sheet) are commonly quenched in a medium that provides somewhat slower cooling. This medium may be water at 65 to 80 °C (150 to 180 °F), boiling water, an aqueous solution of polyalkylene glycol, or some other fluid medium such as forced air or mist.

If appreciable precipitation during cooling is to be avoided, two requirements must be satisfied. First, the time required for transfer of the load from the furnace to the quenching medium must be short enough to preclude slow precooling into the temperature range where very rapid precipitation takes place. For alloy 7075, this range was determined to be 400 to 290 °C (750 to 550 °F), and some sources quote this range (or a slightly different range) as the most critical range for quenching of any aluminum alloy. Later work has shown that the most critical range is alloy-dependent, and as will be discussed in detail under "Quench-Factor Analysis ," significant errors can result from the assumption that precipitation is negligible outside of a so-called "critical range."

The second requirement for avoidance of appreciable precipitation during quenching is that the volume, heat-absorption capacity, and rate of flow of the quenching medium be such that little or no precipitation occurs during cooling. Any interruption of the quench that might allow reheating into a temperature range where rapid precipitation can occur must be prohibited.

For maximum dimensional stability, some forgings and castings are fan cooled or still-air cooled. In such instances, precipitation-hardening response is limited, but satisfactory values of strength and hardness are obtained. Extrusions produced without separate solution heat treatment can be air or mist quenched, but thicker sections may require water quenching by immersion or spraying. Alloys that are relatively dilute, such as 6063 and 7005, are particularly well suited to air quenching, and their mechanical properties are not greatly affected by its low cooling rate. Lower quenching rates are also employed for forgings, castings, and complex shapes to minimize warpage or other distortion and the magnitude of residual stresses developed as a consequence of temperature nonuniformity from surface to interior.

Effect of Quench Rate on Properties. As a broad generalization, the highest strengths attainable and the best combinations of strength and toughness are those associated with the most rapid quenching rates. Resistance to corrosion and stress-corrosion cracking are other characteristics that are generally improved by maximum rapidity of quenching. Some of the alloys used in artificially aged tempers, and in particular the copper-free 7*xxx* alloys, are exceptions to this rule. The effect of quench rate on mechanical properties may also depend on the desired temper. In the underaged condition, for example, a slow quench rate is more detrimental on ductility and fracture toughness. Strength would be more affected after near-to-peak aging.

Because of these effects, much work has been done over the years to understand and predict how quenching conditions and product form influence properties. The relative effects of quench methods can be compared in terms of average quench rates. In Fig. 3, for example, the effects of quenching on the yield strength of four alloys are compared in terms of average quenching rates through the range from 400 to 290 °C (750 to 550 °F). For alloys relatively high in sensitivity to quenching rate, such as 7075, rates of about 300 °C/s (540 °F/s) or higher are required in order to obtain near-maximum strength after precipitation heat treatment. The other alloys in Fig. 3 maintain their strengths at cooling rates as low as about 100 °C/s (180 °F/s). Similar comparisons in terms of average quench rates are shown in Tables 4 and 5.

Table 4 Effect of average quench rate on tensile properties of aluminum-lithium alloy 2090

Average quench rate at center of plate	Condition	Yield strength[a]		Tensile strength[a]		Elongation[a], %
		MPa	ksi	MPa	ksi	
0.5 °C/s (13 mm plate, air cooled)	As-quenched 6% stretch + aged 8 h at 190 °C	162		334		**2**
		448		513		**5**
36 °C/s (38 mm plate, quenched in room-temperature water)	As-quenched 6% strecth + aged 8 h at 190 °C	128		312		**12**
		338		476		**6**
46 °C/s (13 mm plate, quenched in boiling water)	As-quenched 6% stretch + aged 8 h at 190 °C	138		331		**16**
		530		570		**9**
48 °C/s (13 mm plate, quenched in room-temperature water)	As-quenched 6% stretch + aged 8 h at 190 °C	139		331		**17**
		526		570		**7**
85 °C/s (13 mm plate, quenched in ice brine)	As-quenched 6% stretch + aged 8 h at 190 °C	135		349		**19**
		535		**575**		**7**

(a) Data are averages from 4 specimens.

Table 5 The effect of quench rate on the mechanical properties of age-hardened aluminum-lithium alloy 8090

Alloy composition	Cooling from solution treatment[a]	Stretch, %	Aging treatment	Yield strength[b]		Ultimate tensile strength[b]		Elongation in 50 mm (2 in.)[b], %
				MPa	ksi	MPa	ksi	
Al-2.28Li-0.86Cu-0.90Mg-0.13Zr-0.13Fe-0.06Si	Air cool (~0.25 °C/s)	2	190 °C for 16 h	380	55	446	64.5	**7.7**
		4	170 °C for 24 h	401	58	465	67.5	**6.0**

	Polymer quench (~18 °C/s)	2	190 °C for 16 h	415	60	481	70	**8.0**

	Water quench (~120 °C/s)	2	190 °C for 16 h	464	67	535	77.5	**8.2**
		4	**170 °C for 24 h**	**448**	**65**	**517**	**75**	**6.3**

(a) Solution treatment of 550 °C (1020 °F) for 1 h.

(b) Data are averages from two specimens.

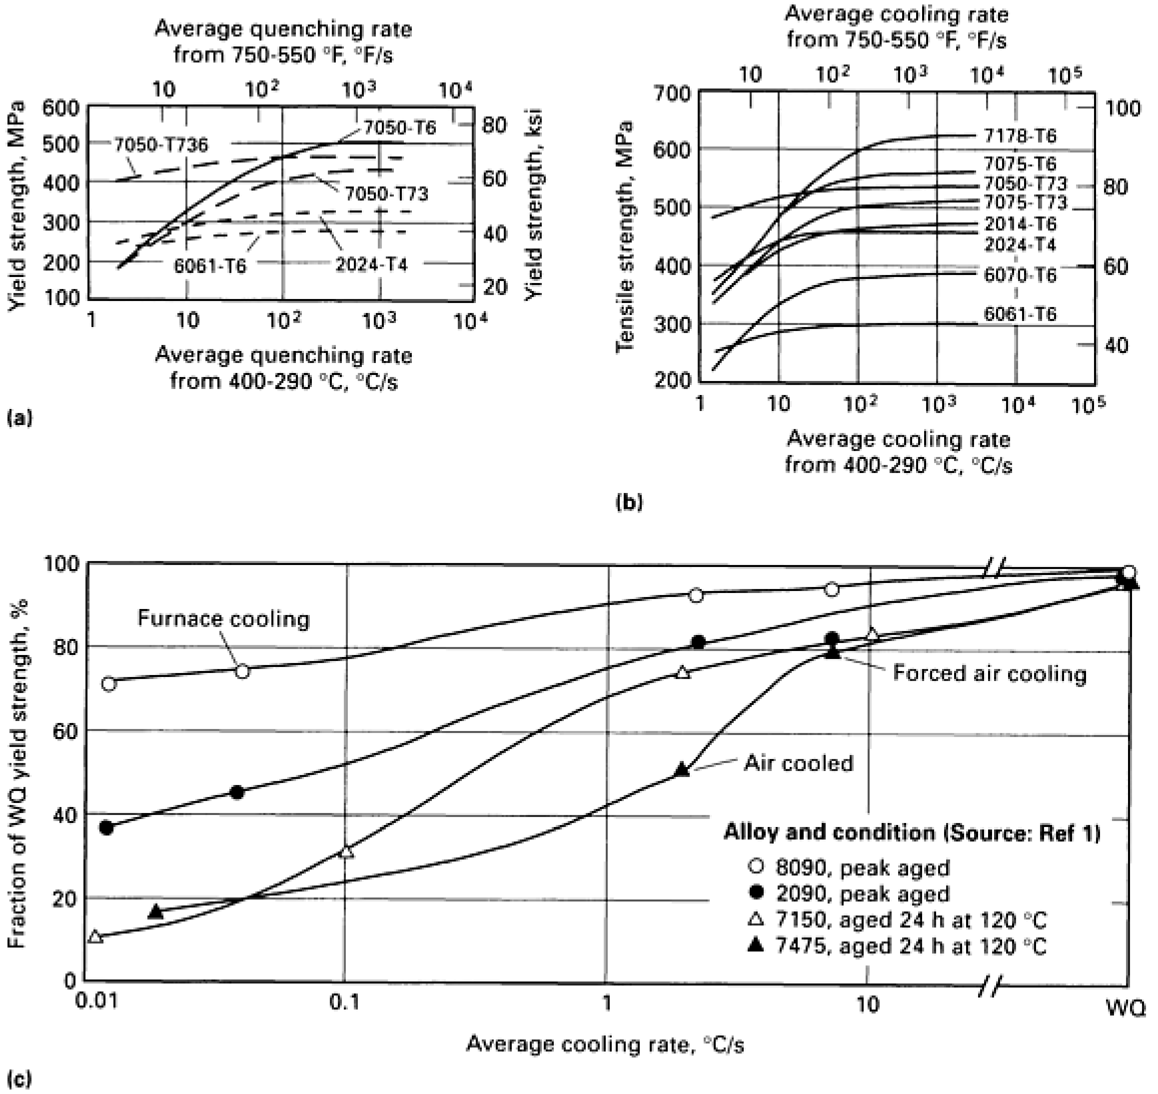

Fig. 3 Quench sensitivity of various aluminum alloys as a function of average quench rates. (a) Yield strength after aging of four wrought alloys. (b) Tensile strength after aging of eight wrought alloys. (c) Relative quench sensitivity of two aluminum-lithium alloys (2090 and 8090, both solution treated for 1 h at 520 °C, or 970 °F) and two Zn-Mg-Cu aluminum alloys (7150 and 7475, both solution treated for 40 min at 480 °C, or 895 °F)

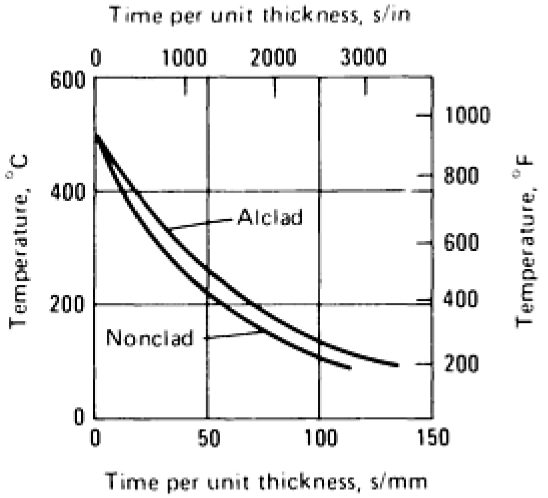
Average quench rates are useful in comparing experimental results from various quench methods. In Table 4, for example, a severe reduction in strength occurred at the average quench rate of 36 °C/s (65 °F/s). However, average quench rates only compare results in a "critical" temperature range, where precipitation is most likely to occur. This method is not entirely accurate, because significant precipitation can also occur outside the specified critical temperature range of average quench rates. Moreover, for high-strength alloys, toughness and corrosion resistance may be impaired without significant loss of tensile strength.

Therefore, a more sophisticated comparison, known as quench-factor analysis, is needed for quantitative property prediction or property optimization. Quench-factor analysis, as discussed in a later section, is useful when cooling rates are nonuniform.

Delay in Quenching. Whether the transfer of parts from the furnace to the quench is performed manually or mechanically, it must be completed in less than the specified maximum time. The maximum allowable transfer time or "quench delay" varies with the temperature and velocity of the ambient air and the mass and emissivity of the parts. From cooling curves such as those illustrated in Fig. 4, maximum quench delays (see table accompanying Fig. 4) can be determined that will ensure complete immersion before the parts cool below 400 °C (750 °F). MIL-H-6088 specifies maximum quench delays for high-strength alloys of 5, 7, 10, and 15 s for thickness ranges of up to 0.016 in. (0.41 ram),

0.017 to 0.031 in. (0.43 to 0.79 mm), 0.032 to 0.090 in. (0.81 to 2.29 mm), and over 0.090 in., respectively. Quench delay is conservatively defined as commencing "when the furnace door begins to open or the first corner of a load emerges from a salt bath" and ending "when the last corner of the load is immersed in the water quench tank." Recommended maximum quench-delay times are listed in Table 2. However, exceeding the maximum delay time is permitted if temperature measurements of the load prove that all parts are above 415 °C (775 °F) when quenched. The C-curves used in quench-factor analysis can also assist in determining a maximum allowable delay.



Thickness		Maximum quench delay, s	
mm	**in.**	**Alclad**	Nonclad
0.41	0.016	6.4	**4.4**
0.51	0.020	8.0	**5.5**
0.64	0.025	10.0	**6.8**
0.81	0.032	12.8	**8.8**
1.02	**0.040**	**20.0**	**11.0**

Fig. 4 Cooling curves for alclad and nonclad aluminum products cooled from 495 °C (920 °F) in forced air. Air temperature, 25 °C (80 °F); air velocity, 2.3 m/s (450 ft/min). Tabulated values of quench delay (maximum delay before the material being quenched has cooled below 400 °C, or 750 °F) were determined from cooling curves shown.

It is relatively easy to control quench delay in day-to-day operations by using a stopwatch or, if necessary, by attaching thermocouples to parts. However, although the cooling rate between 400 and 260 °C (750 and 500 °F) is most critical and must be extremely high for many high-strength alloys, it cannot be directly measured in production operations. It is usual

to rely on standardized practices, augmented by results of tension tests and tests of susceptibility to intergranular corrosion.

Water-immersion quenching normally is controlled in practice by stipulating maximum quench-delay time and maximum water temperature. The first requirement controls the cooling rate during transfer and, for high-strength alloys, often is based on the criterion of complete immersion before the metal cools below 415 °C (775 °F). This specification of 415 °C (775 °F) is based on a critical temperature for alloy 7075, which has one of the more severe C-curves (Fig. 5). Therefore, the criterion for complete immersion of other alloys might be based on a temperature lower than the 415 °C (775 °F) specification, depending on the characteristics of the particular C-curve.

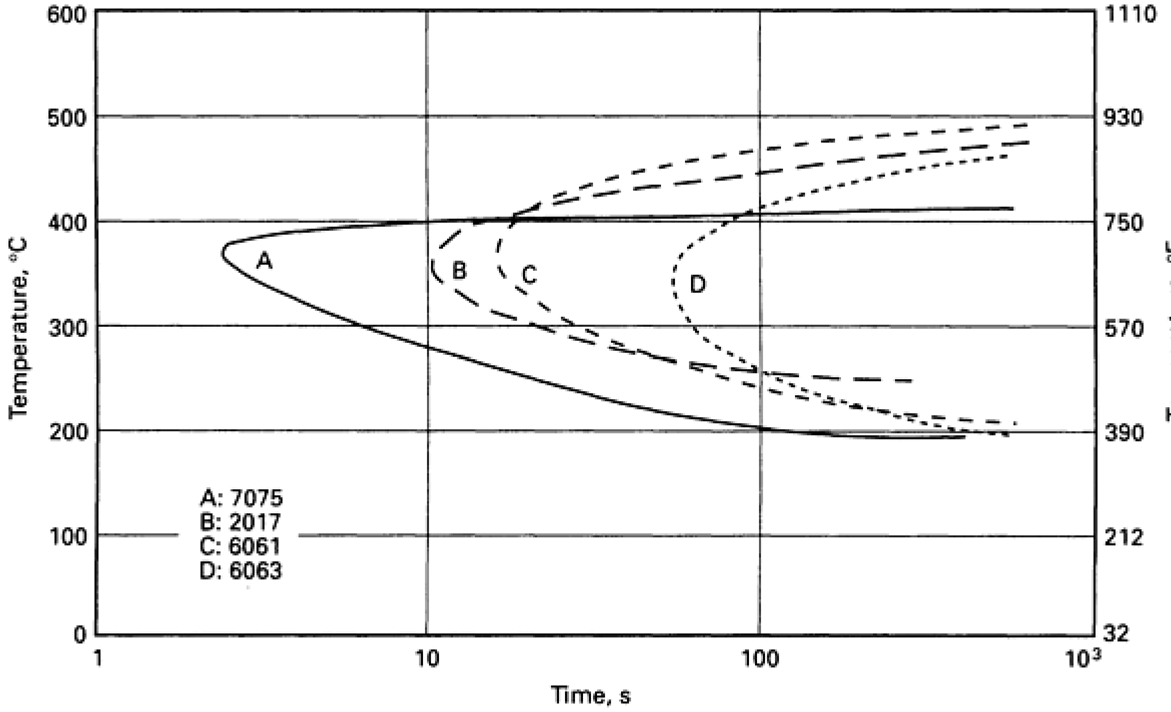


Fig. 5 Time-temperature-property curves at 95% of maximum tensile stress for various alloys. See the section "Quench-Factor Analysis" for discussion. Source: Ref 2

The second requirement controls the cooling rate during immersion. MIL-H-6088 specifies that for water-immersion quenching, except quenching of forgings and castings, the temperature of the water shall not exceed 38 °C (100 °F) upon completion of quenching. This requirement controls both the temperature of the quench water prior to immersion and the ratio of the combined mass of load and rack to the volume of water. However, to ensure adequate quenching effectiveness, it is necessary also that the cooling fluid flow past all surfaces of each part during the first few seconds after immersion. Before parts enter the furnace, their placement in racks or baskets should be compatible with this requirement. During the first few seconds of quenching, agitation of the parts or the water should be sufficient to prevent local increases in temperature due to the formation of steam pockets.

In one application, it was found that 2024-T4 plates 13 by 760 by 760 mm ($\frac{1}{2}$ by 30 by 30 in.), quenched singly into a large volume of still water, were quite susceptible to intergranular corrosion. This susceptibility disappeared completely when the quenching practice was modified by adding sufficient agitation to break up the insulating blanket of steam that formed on the surface of the hot metal. Quenching practices for small parts such as fasteners and hydraulic fittings have been modified for the same reason. Dumping in bulk from baskets has been replaced by methods, such as the use of shaker hearth furnaces or special racking, which permit parts to be quenched singly.

Spray Quenching. For spray quenching, the quench rate is controlled by the velocity of the water and by volume of water per unit area per unit time of impingement of the water on the workpiece. Rate of travel of the workpiece through the sprays is an important variable.

Local increases in temperature that occur within the first few seconds of quenching, caused by a phenomenon such as plugged spray nozzles, are particularly deleterious. The remaining "internal heat" may be sufficient to reheat the surface region. When this happens, a large loss in strength occurs at the previously quenched surface. The loss of strength in the affected area of a heavy part is much more severe than that caused by an inadequate quenching rate alone. This is illustrated for 75 mm (3 in.) thick 7075-T62 plate in Fig. 6, which compares, at various depths, the properties of a plate for which quenching was interrupted on one side after 3 s with those of a plate that was quenched from one side only.

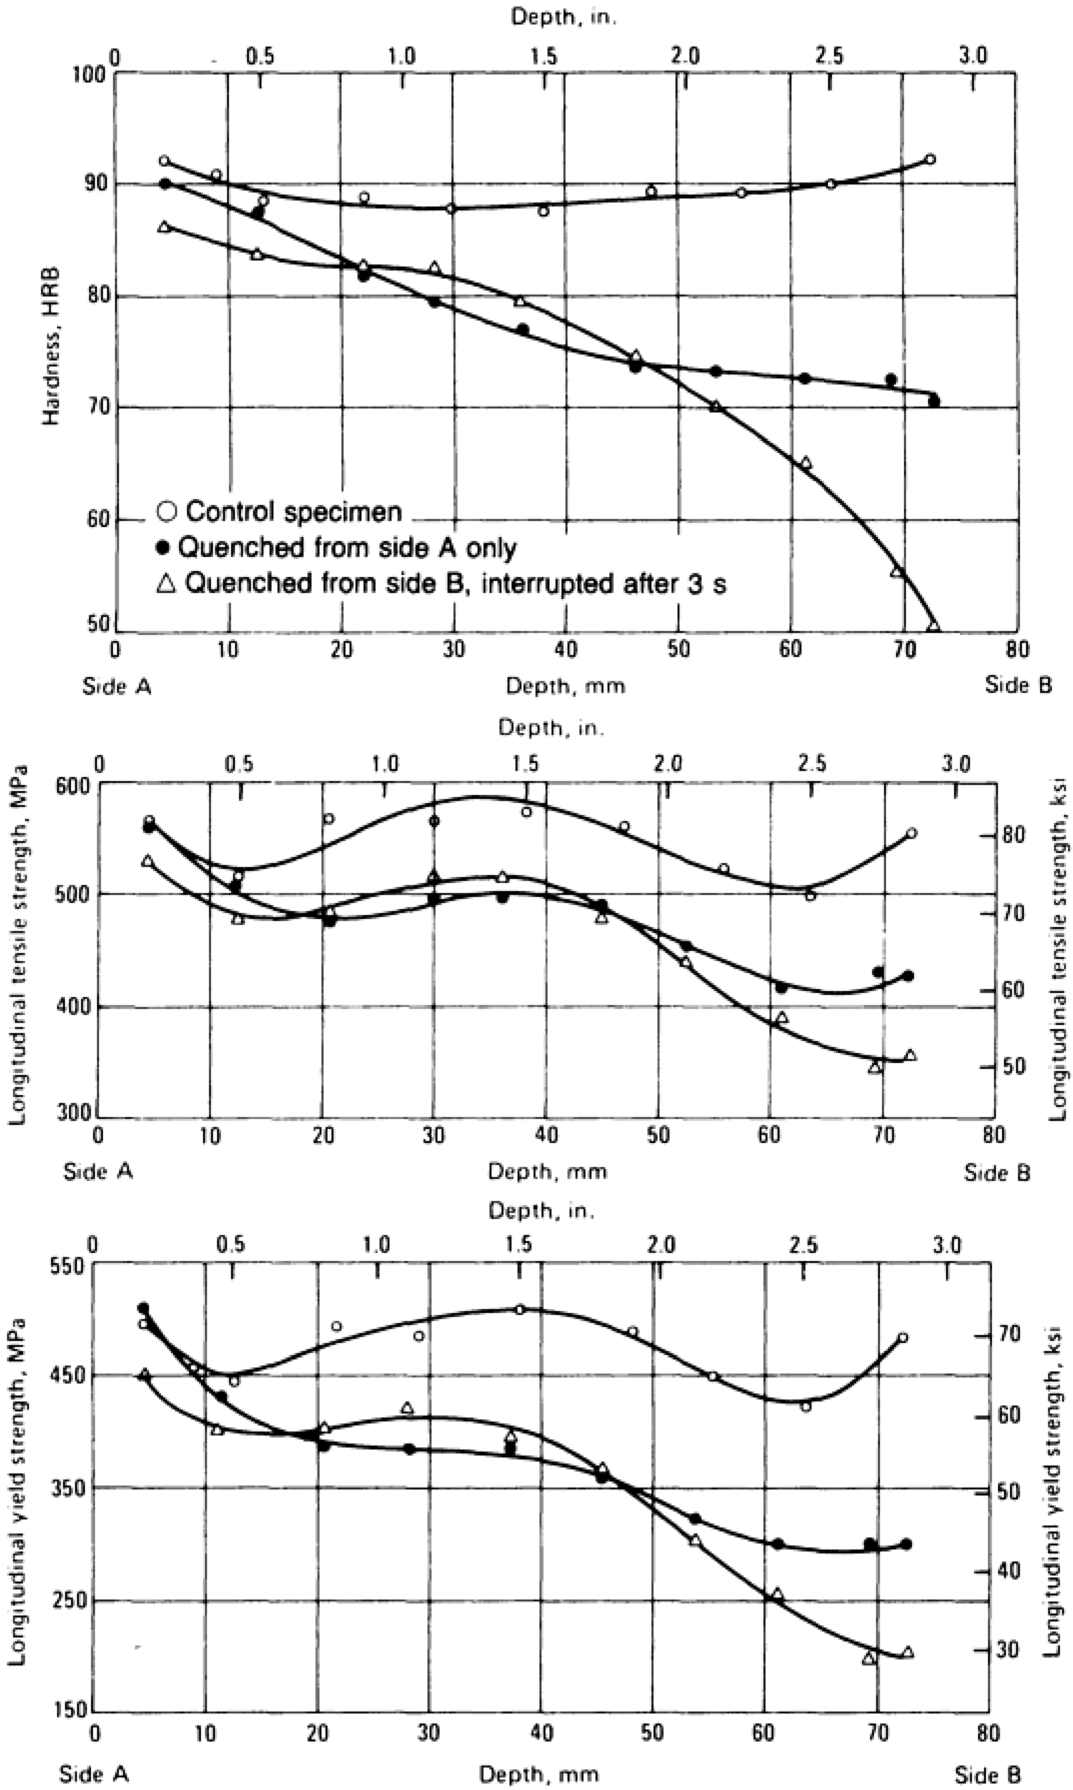

Fig. 6 Through-thickness property variations due to quench rate and temperature-rise effects in 7075-T62

plate 75 mm (3 in.) thick

Quench Severity and Quenchant Selection. Quench severity is commonly expressed in terms of an *H*-value (or Grossmann number), where the *H*-value is related to the thermal conductivity (k) of the part(s) and the coefficient of heat transfer (C) between the quenchant and the part. These quantities are related by the equation $H = C/2k$, where the coefficient of heat transfer (C) is affected by the quenchant velocity at the surface of the part and several inherent characteristics of the quenchant (such as quenchant boiling point, viscosity, density, thermal conductivity, and specific heat).

Water, which is the most widely used and effective quenching medium, can obtain cooling rates up to about 200 °C/s (400 °F/s) at the midplane of 25 mm (1 in.) thick aluminum alloy plate (see the dashed line in Fig. 7). No rates higher than those defined by this line have been observed, although rates approaching them were measured with impinging spray quenches. Lower cooling rates are achieved by immersion in heated water (Fig. 7) or by reducing the velocity of the quenchant around the part (Table 6). Cooling rates can also be reduced by lowering surface tension or by increasing the stability of the vapor film around the part.

(a) Polymer quenchants with concentrations of 25%. *K* is equal to the thermal conductivity of the aluminum alloy (7075).

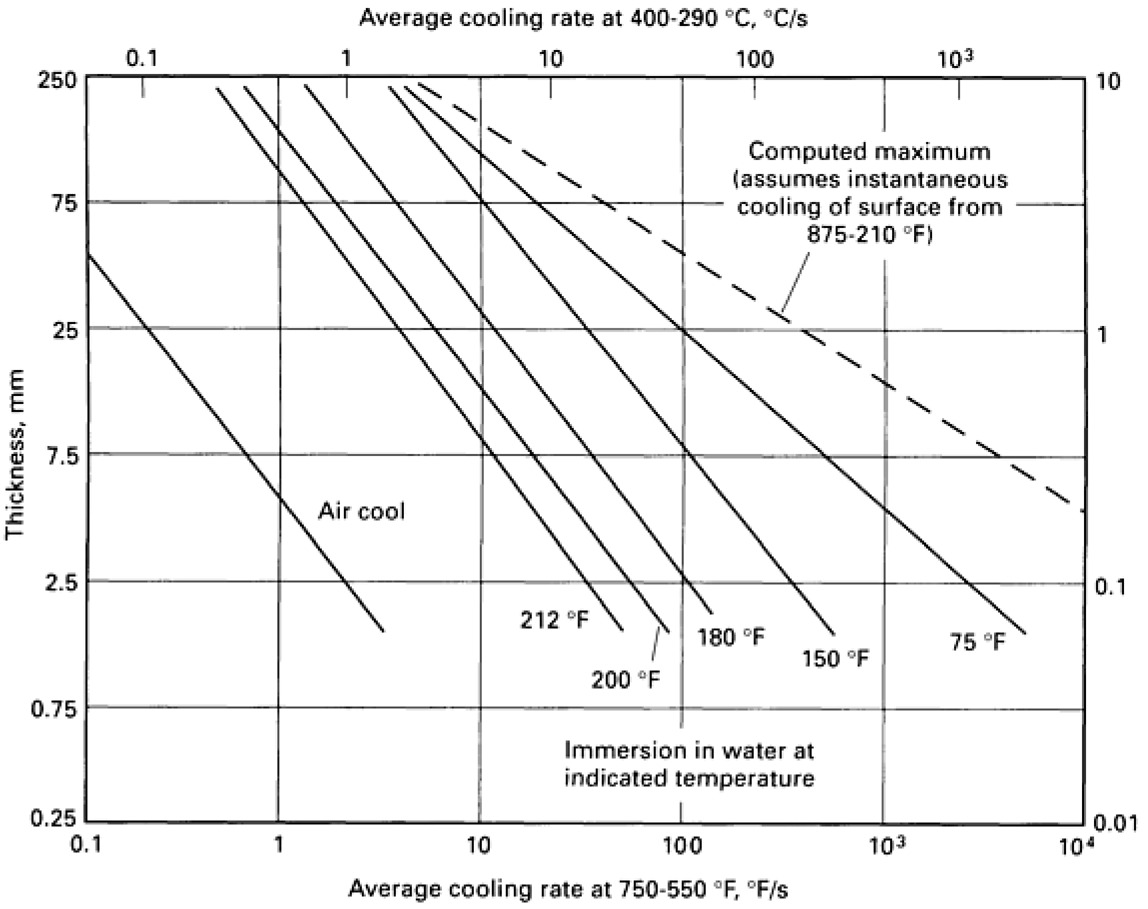

Fig. 7 Effects of thickness and quenching medium on average cooling rates at midplane of aluminum alloy sheet and plate quenched from solution temperatures. The dashed line delineates the maximum cooling rates theoretically obtainable at the midplane of plate, assuming an infinite heat transfer coefficient (*C*) and a diffusivity factor of 1400 cm^2/s. Source: Ref 3

Polymer quenchants, which retard cooling rates by the formation of films around the part, are compared with water in Table 6. The effective film coefficient is essentially the heat transfer coefficient (*C*), which is related to the Grossmann number (*H*). The application of polymer quenchants is covered in AMS specifications 3025 and 2770, although many aluminum and aerospace companies have developed internal specifications that differ from AMS-2770. Typical parameters for quenching wrought products (other than forgings) in glycol-water solutions are presented in Table 7.

Table 7 Limits for quenching in glycol-water solutions

Data are for wrought aluminum alloy products other than forgings.

Other Factors Affecting Quench Rate. Quenching rates are very sensitive to the surface condition of the parts. Lowest rates are observed with products having freshly machined or bright-etched, clean surfaces, or products that have been coated with materials that decrease heat transfer. The presence of oxide films or stains increases cooling rates. Further marked changes can be effected through the application of nonreflective coatings, which also accelerate heating (Fig. 8). Surface roughness exerts a similar effect; this appears related to vapor film stability. The manner in which complex products, such as engineered castings and die forgings, enter the quenching medium can significantly alter the relative cooling rates at various points, thereby affecting mechanical properties and residual stresses established during quenching. Similarly, quenching complex extruded shapes whose wall thicknesses differ widely poses special problems if distortion and stresses are to be minimized. In batch heat-treating operations, placement and spacing of parts on the racks can be a major factor in determining the quenching rates. In immersion quenching, adequate volumes of the quenching medium must be provided to prevent an excessive temperature rise in the medium. When jet agitation is used to induce water flow between parts, jets should not impinge directly and cause rapid localized cooling.

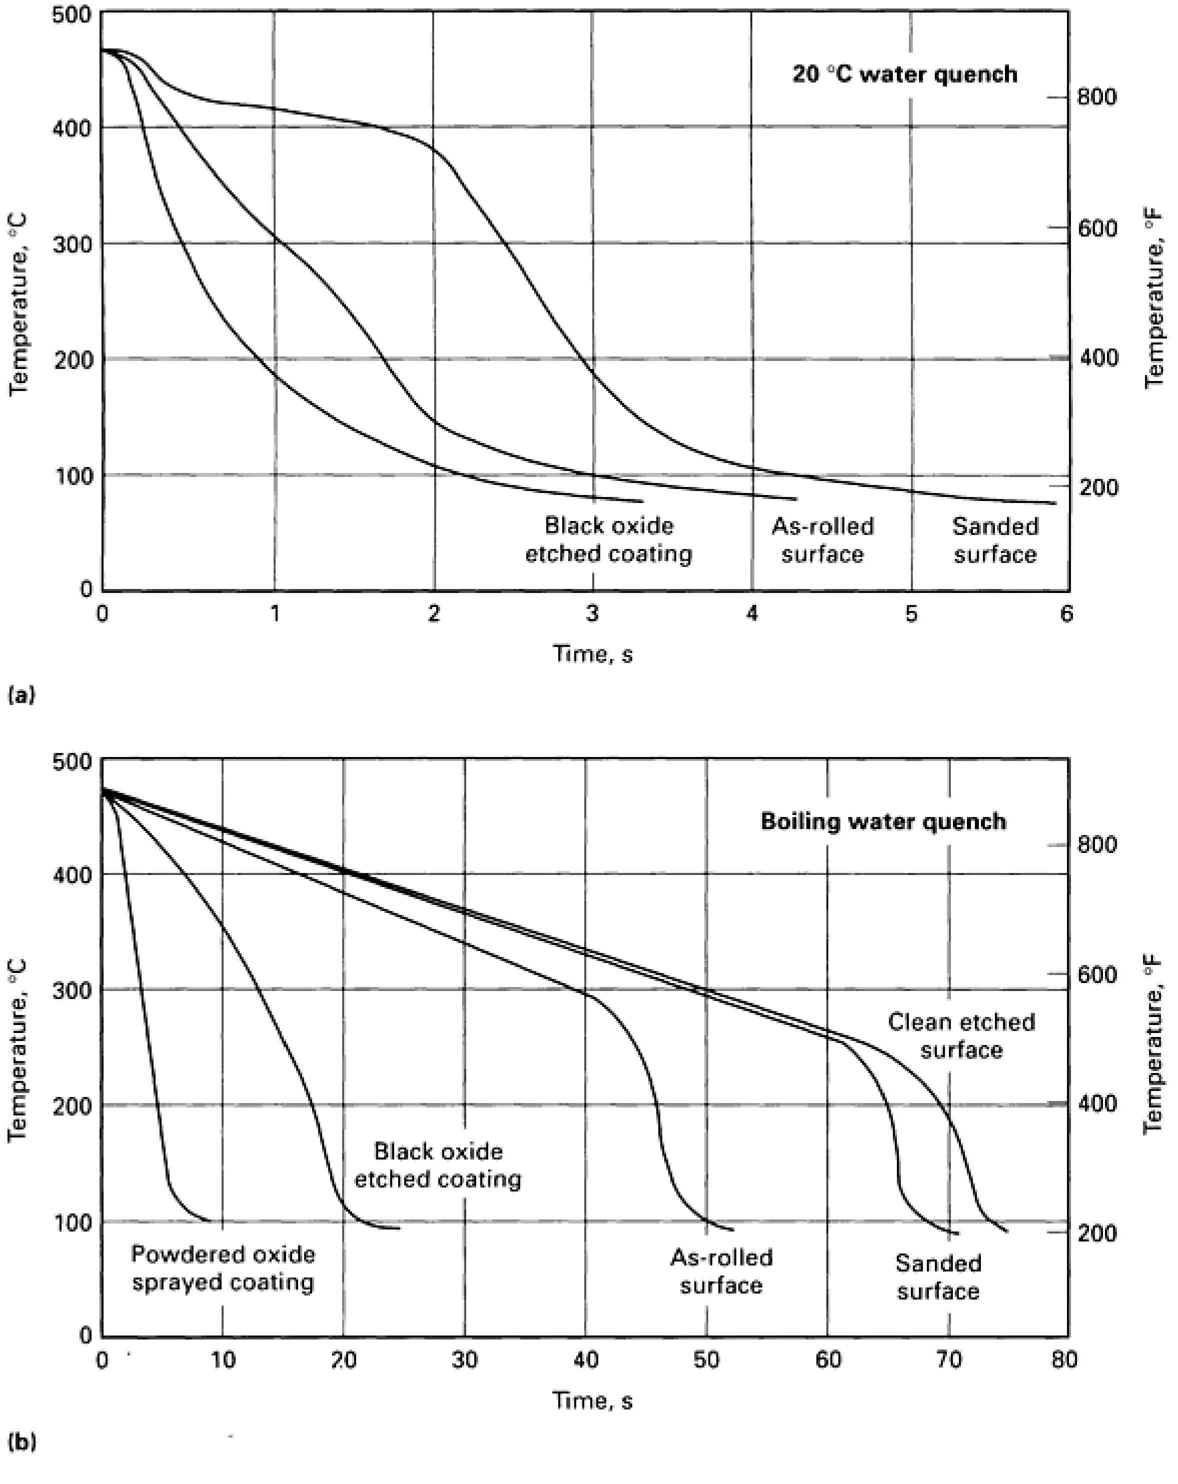

Fig. 8 Effect of surface conditions on the midplane cooling of a 13 mm (0.5 in.) thick plate of 7075 from quenching in (a) 20 °C (70 °F) water and (b) boiling water. Source: Ref 5

Quenching to Minimize Residual Stress and Warpage. Although cold-water immersion or flushing is most common, because it produces the most effective quench (and has been required by MIL-H-6088 for 2014, 2017, 2024, 2117, 7075, and 7178 alloys except forgings), it presents problems involving residual stress and warpage.

Residual stresses in heavy sections of aluminum alloys originate from differential thermal expansion during quenching -- that is, the still-warm central material contracts, pulling in the already cooled outer shell. The magnitude of stresses increases with section size, as shown in Fig. 9.

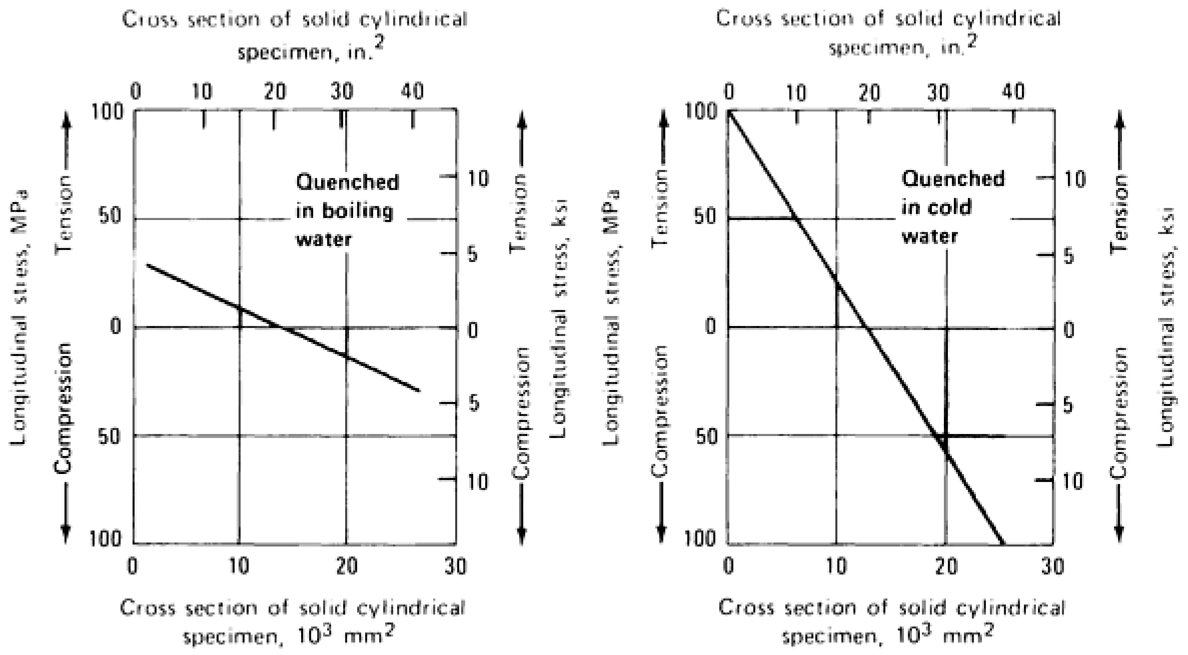

Fig. 9 Effect of quenching from 540 °C (1000 °F) on residual stresses in solid cylinders of alloy 6151

The distribution pattern of residual stresses in as-quenched parts (compression in the outer layers and tension in the central portion) is usually desirable in service. Compressive stresses inhibit failure by fatigue and stress corrosion--two mechanisms that initiate in the outer fibers. Unfortunately, metal-removal operations required after heat treating often expose material that is stressed in tension. Also, metal-removal operations that are asymmetrical (with respect to residual stresses) cause distortion by redistributing residual stresses. When close-tolerance parts are being fabricated, the resulting warpage can be costly and difficult to correct.

Although service performance is sometimes a factor, the major incentive for reducing residual stress differentials has been a reduction in warpage during machining or an improvement in shape before machining.

One approach to reducing the cooling-rate differential between surface and center is the use of a milder quenching medium--water that is hotter than that normally used or water-glycol solutions. Boiling water, which is the slowest quenching medium used for thick sections, is sometimes employed for quenching wrought products even though it lowers mechanical properties and corrosion resistance. Quenching of castings in boiling water, however, is standard practice, and is reflected in design allowables.

Another approach to the minimization of residual stresses that is generally successful consists of rough machining to within 3.2 mm (0.125 in.) or less of finish dimensions, heat treating, and then finish machining. This procedure is intended to reduce the cooling-rate differential between surface and center by reducing thickness; other benefits that accrue if this technique is used to reduce or reverse surface tension stresses in finished parts are improvements in strength, fatigue life, corrosion resistance, and reduced probability of stress-corrosion cracking.

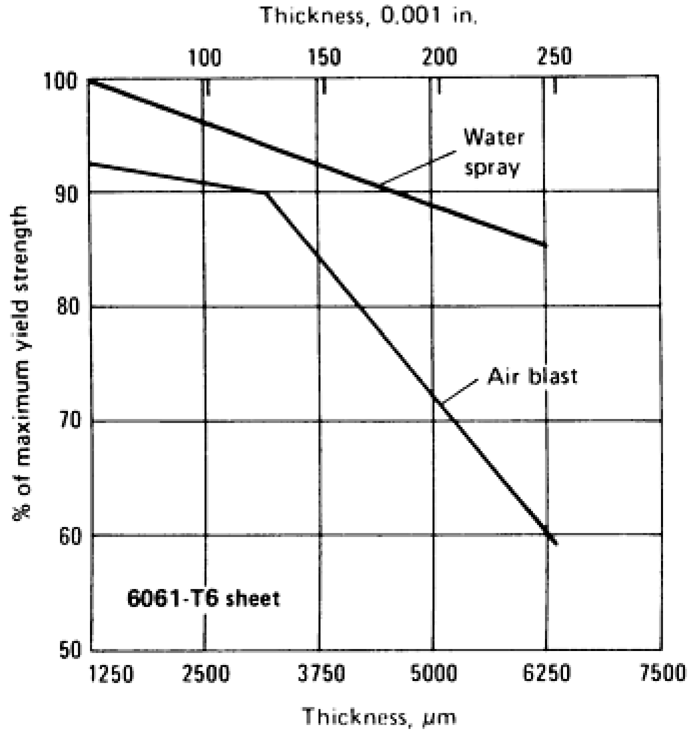
Several factors (especially quenching warpage) sometimes preclude general use of this procedure. The thinner and less symmetrical a section, the more it will warp during quenching, and the residual stresses resulting from straightening of warped parts (plus straightening costs) often are less desirable than the quenching stresses. Holding fixtures and die quenching may be helpful, but precautions must be taken to ensure that they do not retard quenching rates excessively. Other factors that must be considered are the availability of heat-treating facilities and whether or not the advantages of such a manufacturing sequence offset the delay and cost entailed in a double-machining setup.

Warpage of thin sections during quenching is also a problem. Even in the same load, symmetry of cooling usually varies significantly among identical parts and the resultant inconsistent warpage usually requires costly hand straightening. Consequently, a significant amount of effort has been devoted to reducing or eliminating warpage by changing racking positions to achieve symmetry of cooling.

For sheet-metal parts, one manufacturer uses a double screen floor in the quenching rack to reduce the force of initial contact between water and parts. Others allow parts to "free fall" from rack to quench tank. Spacing and positioning on the rack are carefully controlled so that parts will enter the water with minimum impact. With this technique, water turbulences must be avoided, because it will often cause parts to float for a few seconds, greatly reducing their cooling rate.

Because of the difficulties encountered with quenching in cold water, milder quenchants have been employed. Indiscriminate use of milder quenchants can have catastrophic effects; however, when their use is based on sound engineering judgment and a metallurgical knowledge of the effects on the specific alloy, significant cost savings or performance improvements can be realized.

The most frequent advantage is the reduction in costly straightening operations and in resultant uncontrolled residual stresses. For example, one aircraft manufacturer utilizes water-spray and air-blast quenching for weldments and complex formed parts made from 6061, an alloy whose corrosion resistance is insensitive to quenching rate. Straightening requirements are negligible and, through careful control of racking and coolant flow, the decrease in mechanical properties is minimized, as shown by the data in Fig. 10.



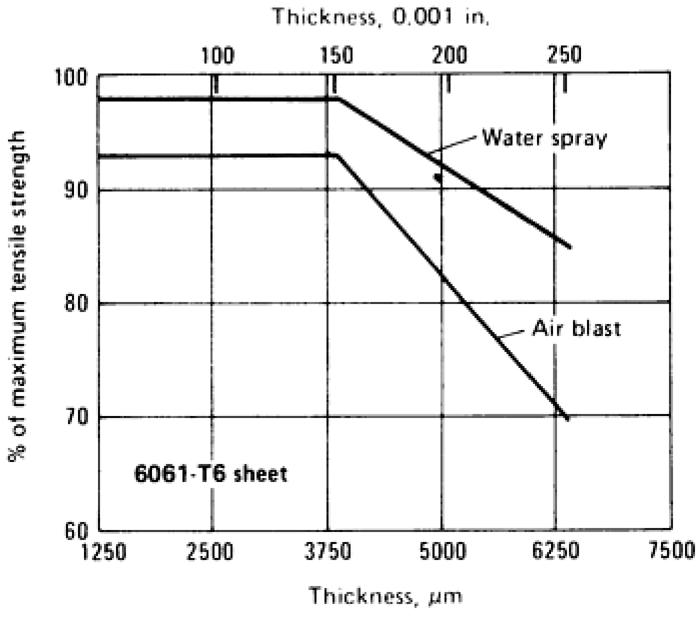


Fig. 10 Effect of quenching medium on strength of 6061-T6 sheet. Water-immersion quench equals 100%. Control of coolant flow will minimize decrease in mechanical properties.

Another development for reducing straightening costs is quenching in water-polymer solutions. Quenching of formed sheet-metal parts in aqueous solutions of polyalkylene glycol or in similar inversely soluble media has significantly reduced the cost of straightening these parts after quenching. The SAE heat-treatment specification AMS-2770 recommends, for several alloys, maximum thicknesses that can be quenched in solutions of specific concentrations while maintaining acceptable property levels. Typical parameters for quenching wrought products (other than forgings) in glycol-water solutions are presented in Table 7. Additional information on polymer quenchants for aluminum alloys can be found in Ref 5.

Forming and Straightening after Quenching. Immediately after being quenched, most aluminum alloys are nearly as ductile as they are in the annealed condition. Consequently, it is often advantageous to form or straighten parts in this temper. Moreover, at the mill level, controlled mechanical deformation is the most common method of reducing

residual quenching stresses. Because precipitation hardening will occur at room temperature, forming or straightening usually follows as soon after quenching as possible. In addition, maximum effectiveness in stress relief is obtained by working the metal immediately after quenching.

Forming and straightening operations vary in degree from minor corrections of warpage to complete forming of complex parts from solution-treated flat blanks. Particular value is gained when enough forming can be done at this stage of processing to eliminate the distortion caused by quenching. However, production operations must be adjusted so that most of the plastic deformation is accomplished before an appreciable amount of precipitation hardening takes place.

Although the most severe forming operations may have to be arranged to avoid natural aging, it often is desirable to allow some natural aging to occur and thus avoid formation of Lüders lines. This condition of nonuniform deformation is most likely to occur shortly after quenching and diminishes significantly after a few hours of natural aging. Complete freedom from Lüders lines, however, may require one or two days of natural aging prior to forming. Thus, the forming operation may have to be timed so as to obtain the most appropriate trade-off of these characteristics for the specific parts involved. Lüders lines also can be reduced by employing low strain rates or by forming at temperatures of 150 to 175 °C (300 to 350 °F).

Residual stresses in sheet-metal parts formed in the quenched condition are higher than those in parts formed in the annealed condition. Consequently, forming in the quenched condition should be selected judiciously for parts that are critical in fatigue (Fig. 11) or stress corrosion.

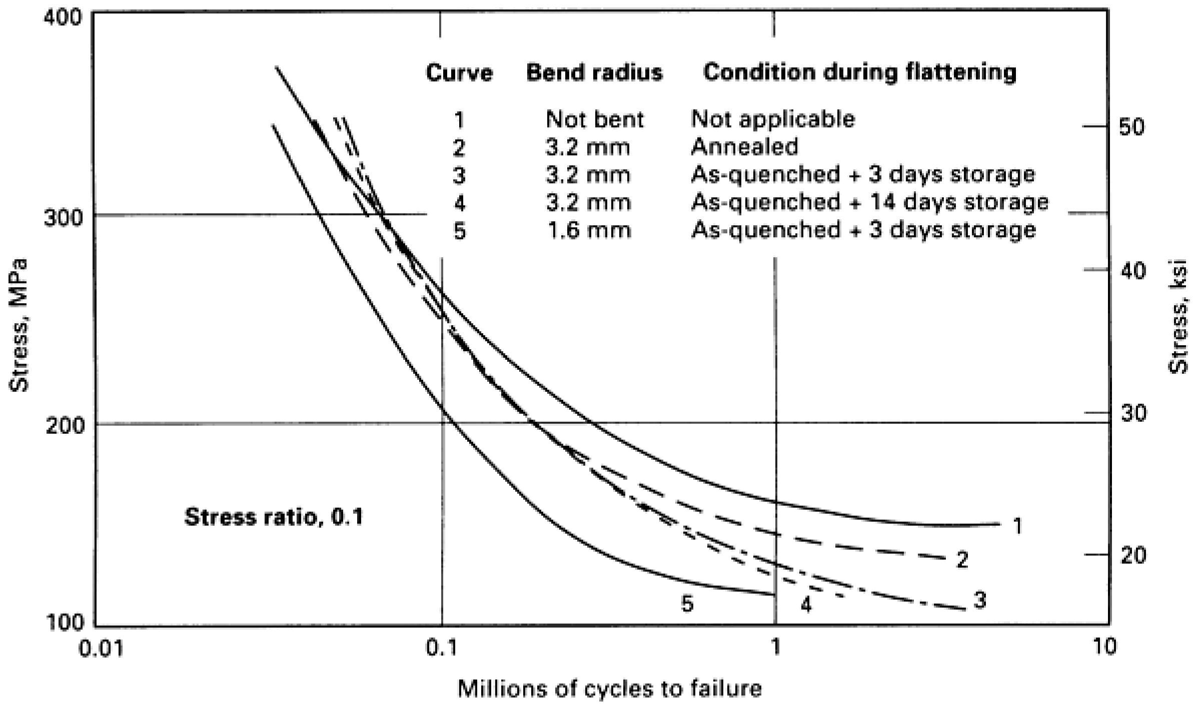

Fig. 11 Fatigue characteristics of 1 mm (0.04 in.) alclad 2024-T4 sheet after 90 ° bending in the annealed condition and subsequent flattening as indicated. Flattening (unbending) was done either in the annealed condition (curve 2), or in the solution-treated and quenched condition (curves 3, 4, 5) with indicated storage times at -18 to -12 °C (0 to 10 °F).

Re-solution heat treatment of parts formed after quenching often causes excessive grain growth in critically strained regions and thus is not recommended.

Quench-Factor Analysis

During the quenching of alloys from a solid-solution temperature condition, the rate of precipitation during quenching is maximized in a so-called "critical" temperature range, because the diffusion of dissolved species and the subsequent

nucleation of precipitates exhibit opposite behavior as a function of temperature. At high temperatures, nucleation rates are small because of the low degree of super-saturation, and so precipitation rates are low despite the high diffusion rates. At low temperatures, diffusion rate is low, and thus precipitation rate is low despite the high degree of supersaturation. At intermediate temperatures, precipitation rate is highest. Consequently, times to produce equal amounts of precipitation follow a C-shape pattern.

Using isothermal quenching techniques, Fink and Willey pioneered the attempts to describe the effects of quench rates with the use of C-curves (Ref 6). The C-curves plot the time required at different temperatures to precipitate a sufficient amount of solute to: reduce strength by a certain amount (Fig. 5); cause a change in the corrosion behavior from pitting to intergranular (Fig. 12); produce a given electrical conductivity (Fig. 13); or relate other properties, such as fracture toughness, to isothermal quench conditions. The nose of the C-curves identifies the critical temperature range (the region of highest precipitation rates). Investigators use critical temperature ranges in conjunction with properties of samples quenched continuously from the solution temperature to compare relative sensitivities of alloys to quenching condition.

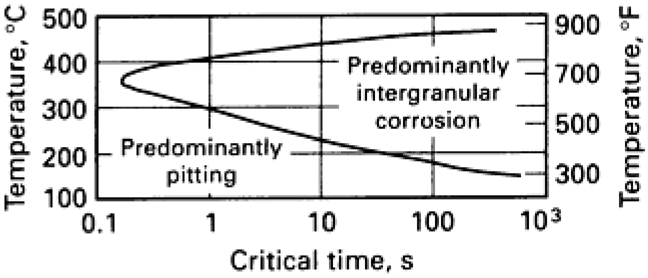

Fig. 12 C-curve indicating type of corrosion attack on 2024-T4 sheet

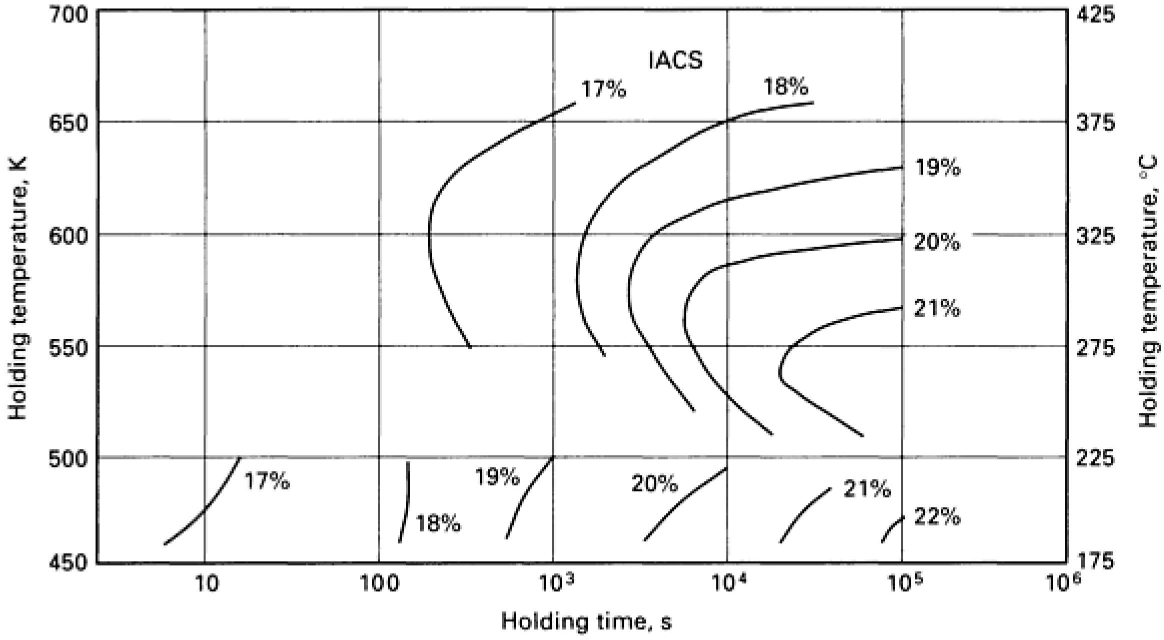

Fig. 13 Change in electrical conductivity of an Al-2.5% Li binary alloy after the following: solution treated at 540 °C (1000 °F) for $\frac{1}{2}$ h, immersed into an adjacent salt or oil bath for the appropriate isothermal holding temperature and time, then quenched into water. Source: Ref 1

Although average quench rates through a critical temperature range can provide reasonable property predictions if cooling rates are fairly uniform, average quench rates cannot provide quantitative predictions when cooling rates vary considerably during the quench. For such instances, a procedure known as "quench-factor analysis" uses information from

the entire C-curve to predict how any quench curve affects properties. Quench-factor analysis is useful in designing suitable limits for quench delays, or when it is not sufficient just to ensure that the cooling curve misses the nose of the C-curve.

The method of quench-factor analysis, as outlined by Evancho and Staley (Ref 7), is based on the determination of a quench factor (τ), which is the major variable in the following equation for precipitation kinetics during continuous cooling:

$$z = 1 - \exp(k\tau) \quad \textbf{(Eq 1)}$$

where z is the fraction transformed and k is a constant related to the transformation fraction of a given C-curve. The quench factor (τ) is defined as:

$$t = \int \frac{dt}{C_t} \quad \textbf{(Eq 2)}$$

where t is time and C_t is critical time as a function of temperature to transform a specified fraction (x). The locus of critical times for a given transformation fraction x (or a percentage of mechanical properties from precipitation) is the C-curve, and the value of k is related to x as follows: $k = \ln(1 - x)$, or $e^k = 1 - x$. Therefore, when $\tau = 1$, the fraction transformed, z , equals the fraction value designated by the C-curve. Equation 2 is based on the assumption that the reaction rate is a function only of the amount transformed and temperature.

The numerical evaluation of the quench factor involves the integration of Eq 2. This integral can be graphically integrated using the method illustrated in Fig. 14. Examples of the way to use the quench factor (τ) in the analysis of quench methods are described below. Neither the average quenching rate through a critical temperature range nor quench-factor analysis can predict strength when the temperature increases during quenching after it is cooled below some critical temperature. Under this condition, strength in the affected areas can be significantly lower than in other areas of the material. The most likely way for this phenomenon to occur is during spray quenching, when the surface cools rapidly by the impinging spray, but reheats by heat flow from the hotter interior when the spray is interrupted.

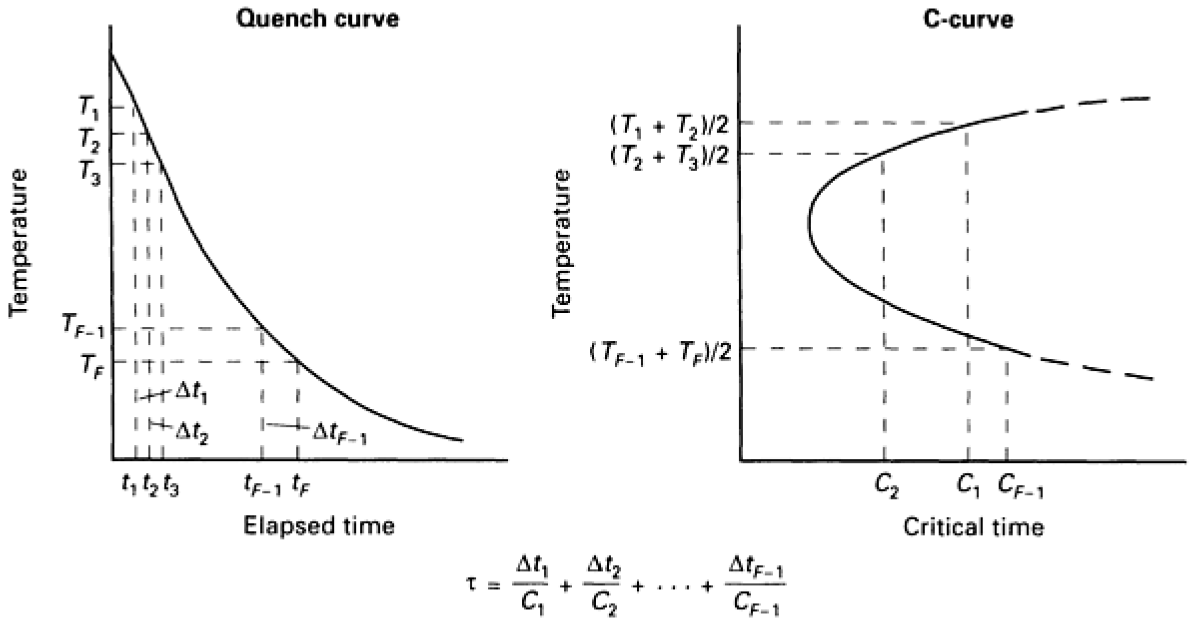

Fig. 14 Method of determining quench factor, τ, using a cooling curve and a C-curve

Predicting Strengths of Thick Products. Effects of the quenching rate on alloy strengths can be represented on a generalized graph of the type shown in Fig. 3, and the expected quenching rates of products having various dimensions can be determined from Fig. 7. Nevertheless, combining these two kinds of information to predict mechanical properties must be done with caution. Inconsistencies were encountered, for example, in correlating properties of thick sections quenched in high-cooling-rate media with properties of thinner sections quenched in media affording milder quenching action. One of the reasons for the inconsistencies is believed to be the different shapes of the cooling curves. This difficulty can be overcome by using quench-factor analysis. The other reason is that the degree of recrystallization and texture of the thick and thin sections may be different.

Predicting Corrosion Behavior. Alloy 2024-T4, for example, is susceptible to intergranular corrosion when a critical amount of solute is precipitated during quenching, but will corrode in the less severe pitting mode when lesser amounts are precipitated. For predicting the effects of proposed quenching conditions on the corrosion characteristics of 2024-T4, the postulated quench curve is drawn and the quench factor is calculated using the C-curve in Fig. 12. Corrosion characteristics are predicted from the plot in Fig. 15. When the quench factor (τ) is less than 1.0, continuously quenched 2024-T4 will corrode by pitting.

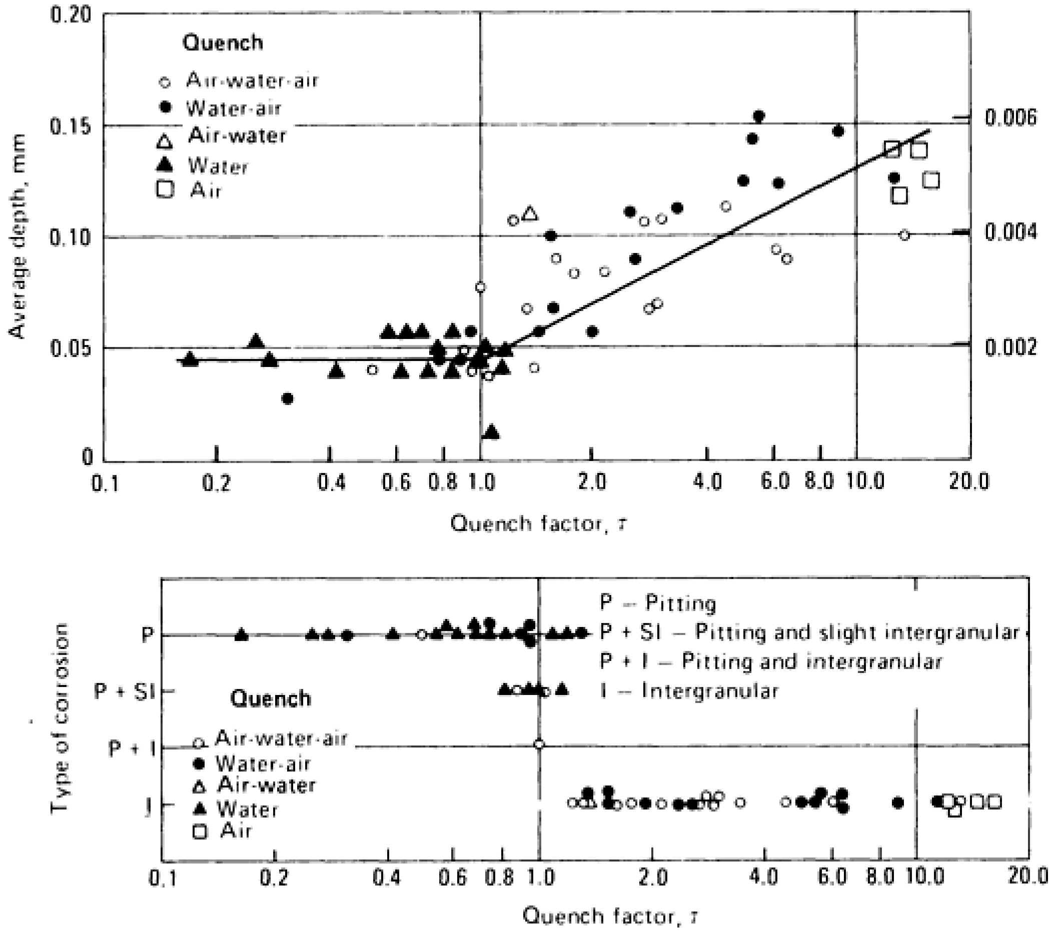

Fig. 15 Type and depth of attack on 2024-T4 sheet versus quench factor

These relationships are applied to studies of effects of proposed changes in quench practice on design of new quenching systems. For example, consider that the goal of a proposed quenching system for 2024-T4 sheet products is to minimize warpage while preventing susceptibility to intergranular corrosion. Warpage occurs when the stresses imposed by temperature differences across the parts exceed the flow stress. As quenching rate decreases, the tendency for large differences in temperature to occur decreases but the tendency for intergranular corrosion to occur increases.

The C-curve in Fig. 12 indicates that quenching rate can be decreased near the solution heat-treating temperature and near room temperature without greatly sacrificing corrosion characteristics, but this information does not provide a quantitative answer. Simple calculations, however, can reveal a multitude of hypothetical cooling curves that provide slow quenching

during a large portion of the quench cycle but sufficiently rapid quenching where critical times are short so that desirable corrosion characteristics are obtained.

As an example, one-, two-, and three-step quench curves that would ensure acceptable corrosion behavior in 2024-T4 sheet (quench factor, 0.99) were calculated. Some of these curves are plotted in Fig. 16. This illustration shows that 2024 can be quenched at a rate of 470 °C/s (850 °F/s) or higher and still develop acceptable corrosion characteristics if the quenching rate is linear from the solution temperature to 150 °C (300 °F). If sheet 3.2 mm (0.125 in.) thick is air-blast quenched (rate of heat removal, 5.68 W/m^2 · °C) to 395 °C (740 °F), however, the quenching rate from 395 to 150 °C must be at least 945 °C/s (1700 °F/s) to maintain the acceptable corrosion behavior. It may also be air-blast quenched to 395 °C (740 °F), spray quenched at 3300 °C/s (6000 °F/s) to 250 °C (480 °F), then air-blast quenched to 150 °C (300 °F).

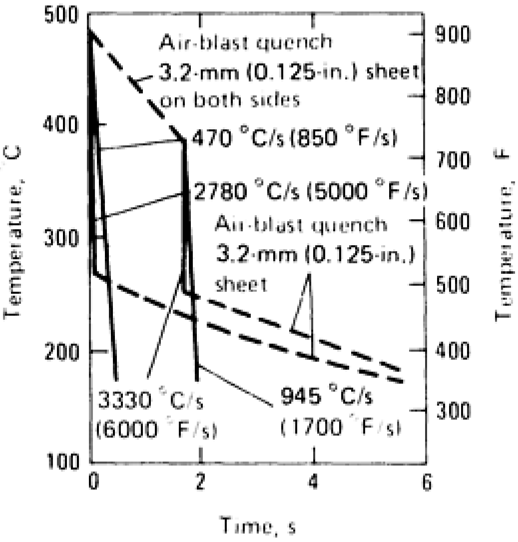

Fig. 16 Quench curves for 2024-T4 sheet, to eliminate susceptibility to intergranular corrosion

Other curves could be drawn, of course, but the important points are that air-blast quenching cannot be continued to more than a few degrees below 395 °C (740 °F) and cannot be initiated at more than a few degrees above 270 °C (520 °F) even if infinite quenching rates are attained from 395 to 270 °C (740 to 520 °F).

Predicting yield strength is more complex than predicting corrosion behavior and requires some knowledge of the relationship between extent of precipitation and loss in ability to develop property. Because attainable strength of precipitation-hardening aluminum alloys is a function of the amount of solute remaining in solid solution after quenching, relationships between strength (σ_x) attainable after continuous cooling and quench factor (τ) can be expressed as follows:

$$\sigma_x = \sigma_{max} \exp (k_1 \tau) \quad \textbf{(Eq 3)}$$

where σ_{max} is the strength attainable with an infinite quenching rate and:

$$t = \int \frac{dt}{C_x} \quad \textbf{(Eq 4)}$$

where t is time and C_x is the C-curve for σ_x--that is, critical time as a function of temperature to reduce attainable strength to x of σ_{max}. The constant k_1 is related to the natural logarithm of x. For example, if τ is based on the C-curve for 99.5% of maximum yield strength, then k_1 = -0.005013 = ln (0.995).

The advantage of predicting yield strength from quench factor instead of from average quenching rate is illustrated by the following comparison. Four specimens of alloy 7075-T6 quenched by various means (see Fig. 17) were selected. Yield strengths were predicted both from average quenching rate between 400 and 290 °C (750 and 550 °F) and from quench

factor. Quench factor was calculated using the C-curve for 99.5% maximum yield strength for 7075-T6 (Fig. 18), and yield strength was estimated from the above equation defining the quench factor (τ) (see Fig. 19).

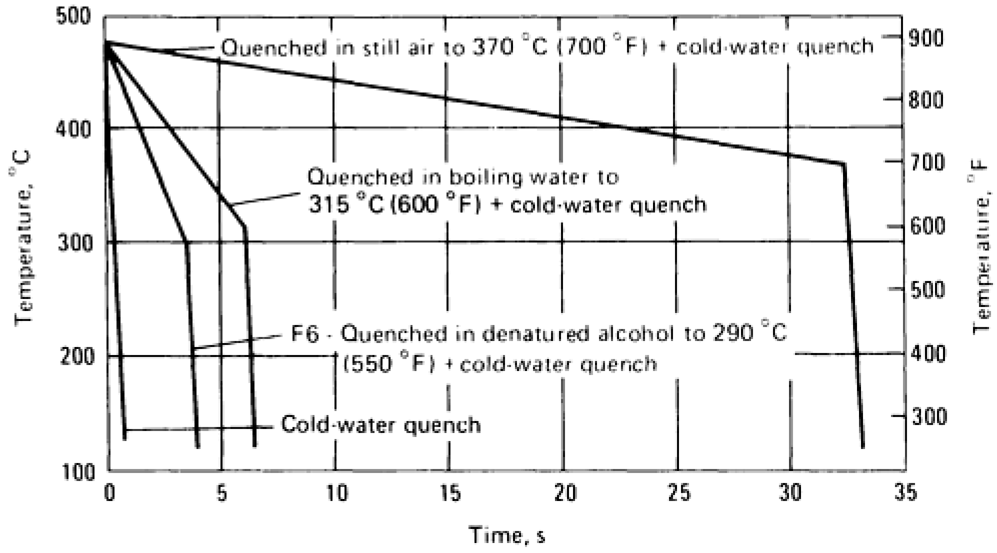

Fig. 17 Cooling curves for 7075-T6 sheet

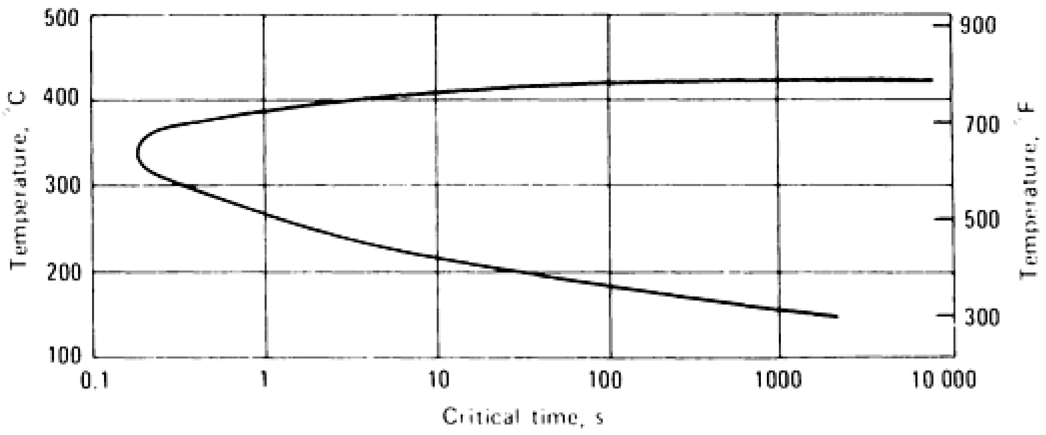

Fig. 18 C-curve for 99.5% maximum yield strength of 7075-T6 sheet

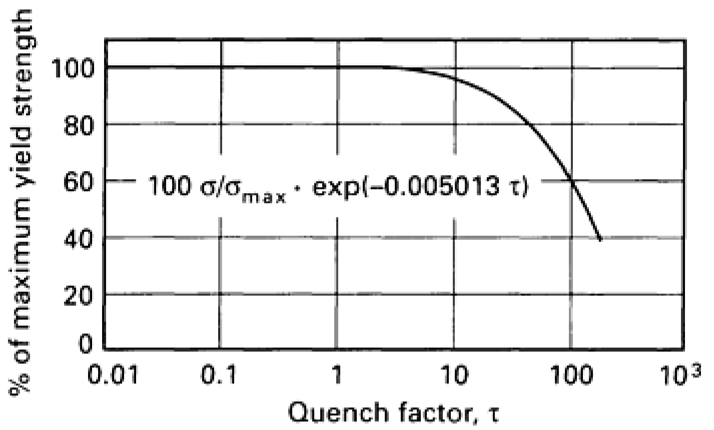

Fig. 19 Yield strength versus quench factor

A comparison of predicted yield strength with actual yield strength is given in Table 8. Yield strengths predicted from quench factor agree very well with measured yield strengths for all specimens, the maximum error being 19.3 MPa (2.8 ksi). Yield strengths predicted from average quenching rates, however, differ from measured values by as much as 226 MPa (32.8 ksi).

Table 8 Yield-strength values for 7075-T6 sheet predicted from cooling curves using average quench rate and quench factor

Quench	**Average quench rate from 400 to 290 °C (750 to 550 °F)**		**Quench factor, τ**	**Measured yield strength**		**Yield strength predicted from average quench rate**		Yield strength predicted from quench factor	
	°C/s	**°F/s**		**MPa**	**ksi**	**MPa**	**ksi**	**MPa**	ksi
Cold water	935	1680	0.464	506	73.4	499	72.4	498	**72.3**
Denatured alcohol to 290 °C (550 °F), then cold water	50	90	8.539	476	69.1	463	67.2	478	**69.4**
Boiling water to 315 °C (600 °F), then cold water	30	55	15.327	458	66.4	443	64.2	463	**67.1**

The advantage of using the quench factor for predicting yield strength from cooling curves is apparent. Cooling curves that have long holding times either above or below the critical temperature range from 400 to 290 °C (750 to 550 °F) cannot be used to predict yield strength from average quenching rate. In such instances, prediction of yield strength on the basis of quench factor is particularly advantageous.

With the use of finite-element analysis, quench factors can also be plotted as a function of Grossmann quench severity values (*H*) or the heat transfer coefficients (*C*) between the quenchant and a particular part (Fig. 20). However, an underlying assumption of both quench-factor analysis and average-cooling-rate estimation is that the only effect of temperature is on the kinetics of precipitation. This assumption is not valid, however, when portions of the metal are quenched locally but reheated significantly before quenching is complete.

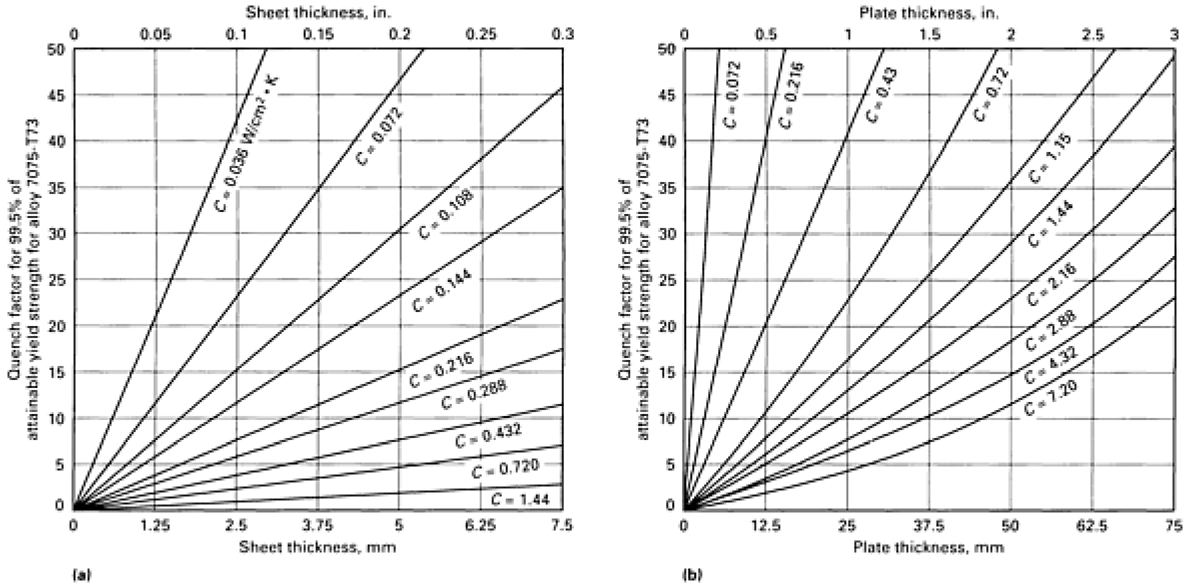

Fig. 20 Plot of quench factors derived from finite element analysis with given product sizes and film (heat transfer) coefficients (*C*). Heat transfer coefficients between the quenchant and part are expressed in $W/cm^2 \cdot K$. Source: Ref 4

Age Hardening

After solution treatment and quenching, hardening is achieved either at room temperature (natural aging) or with a precipitation heat treatment (artificial aging). In some alloys, sufficient precipitation occurs in a few days at room temperature to yield stable products with properties that are adequate for many applications. These alloys sometimes are precipitation heat treated to provide increased strength and hardness in wrought or cast products. Other alloys with slow precipitation reactions at room temperature are always precipitation heat treated before being used.

In some alloys, notably those of the 2*xxx* series, cold working of freshly quenched material greatly increases its response to later precipitation heat treatment. Mills take advantage of this phenomenon by applying a controlled amount of rolling (sheet and plate) or stretching (extrusion, bar, and plate) to produce higher mechanical properties. However, if the higher properties are used in design, reheat treatment must be avoided.

Natural Aging. The more highly alloyed members of the 6*xxx* wrought series, the copper-containing alloys of the 7*xxx* group, and all of the 2*xxx* alloys are almost always solution heat treated and quenched. For some of these alloys--particularly the 2*xxx* alloys--the precipitation hardening that results from natural aging alone produces useful tempers (T3 and T4 types) that are characterized by high ratios of tensile to yield strength and high fracture toughness and resistance to fatigue. For the alloys that are used in these tempers, the relatively high supersaturation of atoms and vacancies retained by rapid quenching causes rapid formation of GP zones, and strength increases rapidly, attaining nearly maximum stable values in four or five days. Tensile-property specifications for products in T3- and T4-type tempers are based on a nominal natural aging time of four days. In alloys for which T3- or T4-type tempers are standard, the changes that occur on further natural aging are of relatively minor magnitude, and products of these combinations of alloy and temper are regarded as essentially stable after about one week.

In contrast to the relatively stable condition reached in a few days by 2*xxx* alloys that are used in T3- or T4-type tempers, the 6*xxx* alloys and to an even greater degree the 7*xxx* alloys are considerably less stable at room temperature and continue to exhibit significant changes in mechanical properties for many years. The differences in rate and duration of changes in tensile yield strength of representative alloys of the three types are illustrated in Fig. 21. Because of the relative instability of the 7*xxx* alloys, the naturally aged temper (after solution heat treatment and quenching) is designated by the suffix letter W. For a specific description of this condition, the time of natural aging should be included (example: 7075-W, 1 month).

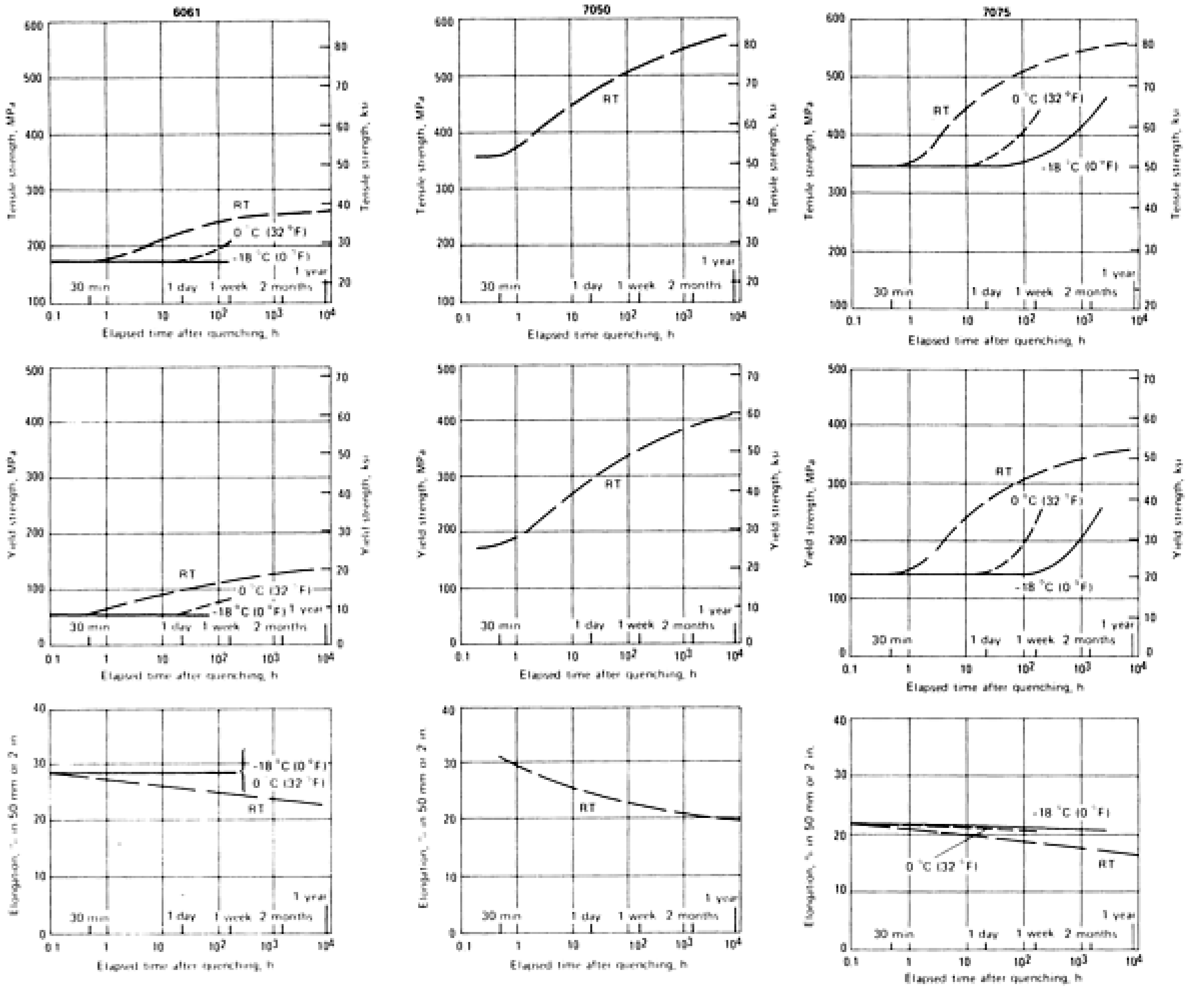

Fig. 21 Aging characteristics of aluminum sheet alloys at room temperature, at 0 °C (32 °F), and at -18 °C (0 °F)

Aging characteristics vary from alloy to alloy with respect to both time to initial change in mechanical properties and rate of change, but aging effects always are lessened by reductions in aging temperature (see Fig. 21). With some alloys, aging can be suppressed or delayed for several days by holding at a temperature of -18 °C (0 °F) or lower. It is usual practice to complete forming and straightening before aging changes mechanical properties appreciably. When scheduling makes this impractical, aging may be avoided in some alloys by refrigerating prior to forming. It is conventional practice to refrigerate alloy 2024-T4 rivets to maintain good driving characteristics. Full-size wing plates for current-generation jet aircraft have been solution heat treated and quenched at the primary fabricating mill, packed in dry ice in specially designed insulated shipping containers and transported by rail about 2000 miles to the aircraft manufacturer's plant for forming.

Unanticipated difficulties may arise as a result of failure to control refrigerator or part temperature closely enough. If opening of the cold box to insert or remove parts is done too frequently, the cooling capacity of the refrigerator may be exceeded. At times, the rate at which heavy-gage parts can be cooled in a still-air cold box has been found to be insufficient. This problem has been solved in one plant by immersing parts in a solvent at -40 °C (-40 °F) before placing them in the refrigerator.

The T3-type tempers are distinguished from T4-type tempers by significant mechanical-property differences resulting from cold work strain hardening associated with certain mechanical operations performed after quenching. Roller or stretcher leveling to achieve flatness or straightness introduces modest strains (on the order of 1 to 4%) that cause changes in mechanical properties (primarily, increases in strength). Further increases in strength can be obtained by cold rolling, additional stretching, combinations of these operations, or for products such as hand forgings, compressive deformation. The tempers produced by these operations followed by natural aging alone (no precipitation heat treatment) are classified as T3-type tempers, and an additional digit is used to indicate a variation in strain hardening that results in significant

changes in properties. In the most recently introduced 2*xxx* aircraft alloy, 2324, high strength is achieved by cold rolling plate to a T39 temper.

Precipitation heat treatments generally are low-temperature, long-term processes. Temperatures range from 115 to 190 °C (240 to 375 °F); times vary from 5 to 48 h.

Choice of time-temperature cycles for precipitation heat treatment should receive careful consideration. Larger particles of precipitate result from longer times and higher temperatures; however, the larger particles must, of necessity, be fewer in number with greater distances between them. The objective is to select the cycle that produces optimum precipitate size and distribution pattern. Unfortunately, the cycle required to maximize one property, such as tensile strength, is usually different from that required to maximize others, such as yield strength and corrosion resistance. Consequently, the cycles used represent compromises that provide the best combinations of properties.

Production of material in T5- through T10-type tempers (see the section on temper designations near the end of this article) necessitates precipitation heat treating at elevated temperatures (artificial aging). Although the hardening precipitate developed by this operation is submicroscopic, structures before and after precipitation heat treatment often can be distinguished by etching metallographic specimens. In aluminum alloys in the solution heat treated and quenched condition, coloration contrast between grains of differing orientation is relatively high, particularly in 2*xxx* series wrought alloys and 2*xx*.0 series casting alloys. This contrast is noticeably decreased by precipitation heat treatment.

Differences in type, volume fraction, size, and distribution of the precipitated particles govern properties as well as the changes observed with time and temperature, and these are all affected by the initial state of the structure. The initial structure may vary in wrought products from unrecrystallized to recrystallized and may exhibit only modest strain from quenching or additional strain from cold working after solution heat treatment. These conditions, as well as the time and temperature of precipitation heat treatment, affect the final structure and the resulting mechanical properties.

Because mechanical properties and other characteristics change continuously with time and with temperature, as shown in Fig. 22(a), 22(b), 22(c), and 22(d) by typical curves for three wrought alloys, treatment to produce a combination of properties corresponding to a specific alloy-temper combination requires one or more rather specific and coordinated combinations of time and temperature, with both parameters being subject to practical limitations. Recommended commercial treatments often are compromises between time and cost factors and the probability of obtaining the intended properties, with consideration of allowances for variables such as composition within specified range and temperature variations within the furnace and load. Use of higher temperatures may reduce treatment time; but if the temperature is too high, characteristic features of the precipitation-hardening process reduce the probability of obtaining the required properties.

Fig. 22(c) Aging characteristics of alloy 6061 sheet

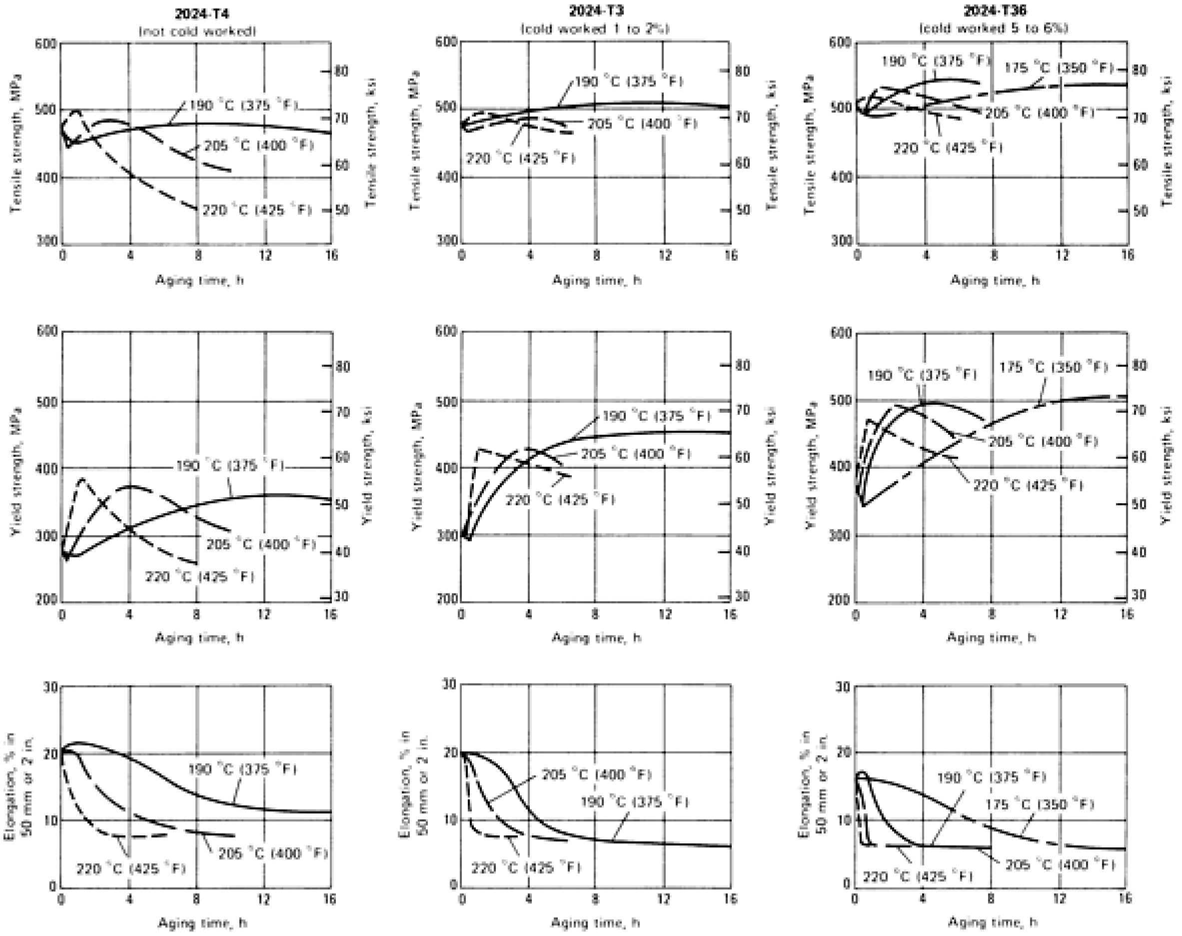

Fig. 22(d) Effects of cold work after quenching and before aging on tensile properties of alloy 2024 sheet

T6 and T7 Tempers. Precipitation heat treatment following solution heat treatment and quenching produces T6- and T7-type tempers. Alloys in T6-type tempers generally have the highest strengths practical without sacrifice of the minimum levels of other properties and characteristics found by experience to be satisfactory and useful for engineering applications. Alloys in T7 tempers are overaged, which means that some degree of strength has been sacrificed or "traded off" to improve one or more other characteristics. Strength may be sacrificed to improve dimensional stability, particularly in products intended for service at elevated temperatures, or to lower residual stresses in order to reduce warpage or distortion in machining. T7-type tempers frequently are specified for cast or forged engine parts. Precipitation heat-treating temperatures used to produce these tempers generally are higher than those used to produce T6-type tempers in the same alloys.

Two important groups of T7-type tempers--the T73 and T76 types--have been developed for the wrought alloys of the 7*xxx* series, which contain more than about 1.25% copper. These tempers are intended to improve resistance to exfoliation corrosion and stress-corrosion cracking, but as a result of overaging, they also increase fracture toughness and, under some conditions, reduce rates of fatigue-crack propagation. The T73-type temper has greatly minimized stress-corrosion cracking of large and complex machined parts made of these alloys, which occasionally occurred with T6-type tempers. The precipitation heat treatment used to produce the T73- and T76-type tempers consist either of a two-stage isothermal precipitation heat treatment or of heating at a controlled rate to a single treatment temperature. The microstructural/electrochemical relationships that are required in order to achieve the desired corrosion-resisting characteristics can be developed by using only a single-stage precipitation heat treatment above about 150 °C (300 °F), but higher strength is obtained by preceding this with a lower-temperature stage or with a slow-controlled heatup. Extended natural aging can provide the same results, but the times required at room temperature are impractical. Either

during the preliminary stage or during slow heatup, a fine, high-density dispersion of GP zones is nucleated. Either the time and temperature of the first step or the rate of heating must be controlled to produce GP zones that will not dissolve but will transform to the η' precipitate when heated to the aging temperature above 150 °C (300 °F). The aging practice that produces the results in the shortest time depends on the GP-zone solvus temperature. This temperature, in turn, depends on vacancy concentration, a factor influenced by solution heat-treating temperature and quench rate, and on composition. If first-step aging time is too short, if first-step aging temperature is too far below the GP-zone solvus, or if heating rates are too high, the GP zones will dissolve above 150 °C (300 °F), and the resultant coarse and widely distributed precipitate will provide lower strength. The T76-type treatments have the same operational sequence but employ second-stage heating only long enough to develop a resistance to exfoliation corrosion higher than that provided by the T6-type tempers. Materials in the T73-type temper also have high resistance to exfoliation corrosion.

Recommended treatments to produce T5- and T6-type tempers, and those of the T7-type employed for dimensional and property stabilization, provide adequate tolerance for normal variations encountered with good operating practices. On the other hand, the T73, T74 (formerly T736), and T76 tempers for alloys 7049, 7050, 7075, 7175, and 7475 involve changes in strength that occur significantly more rapidly at the temperatures employed in the second stage of the T7*x* precipitation heat-treatment cycle compared to the changes occurring at the temperatures employed to produce the T6 temper.

As illustrated in Fig. 23, variations in soak time of several hours, and variations in soak temperature of up to 11 °C (20 °F) from the nominal aging practice of 24 h at 120 °C (250 °F) affect the strength of 7075-T6 by as much as 28 MPa (4 ksi). In contrast, similar variations in second-step soak time and temperature for 7075-T73--that is, variations for 24 h at 165 °C (325 °F)--affect strength by up to 150 MPa (22 ksi).

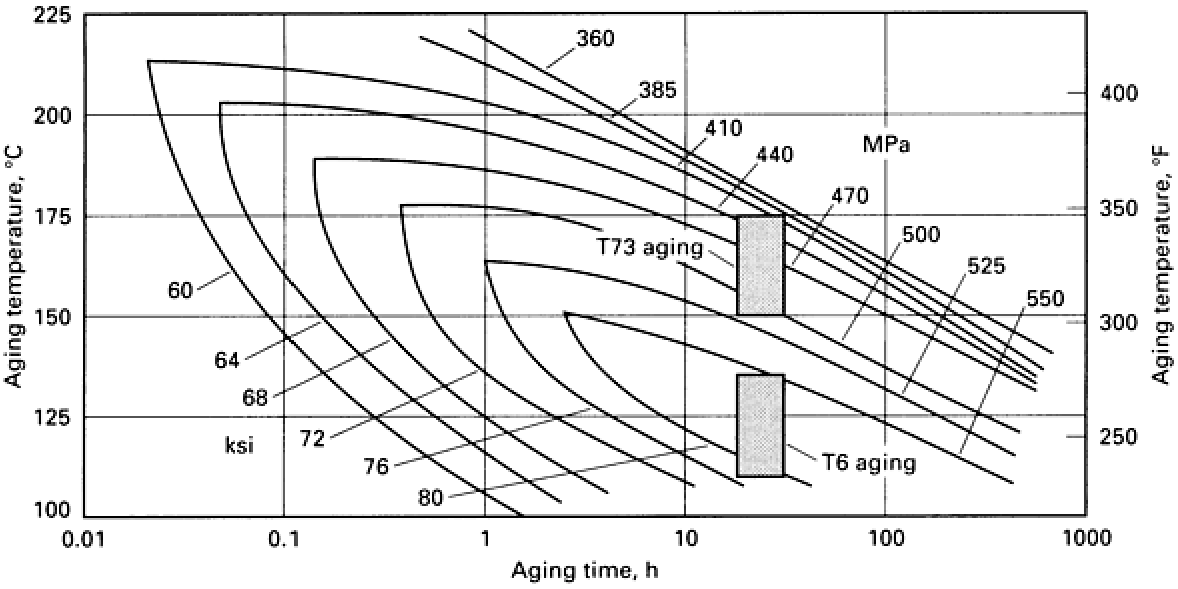

Fig. 23 Iso-yield-strength curves for alloy 7075

Consequently, control of both temperature and time to achieve the mechanical properties and corrosion resistance specified for these tempers is more critical than the control required in producing the T6 temper. Moreover, rate of heating from the first to the second aging step must be considered, because precipitation occurs during this period.

Heat treaters attempt to adjust these new problems by empirically modifying soak times to compensate for precipitation during heating and for effects of soaking at temperatures above or below the nominal. A method has been developed (Ref 8) that permits quantitative compensation for the effects of precipitation during heating and of soaking either above or below the recommended temperature. For overaging, these effects can be described by the following equation:

$$YS = Y \exp - \left(\frac{t_c}{F_{YS}} + q \right) \quad \textbf{(Eq 5)}$$

where *YS* is yield strength; *Y* is a term having units of strength that is dependent on alloy, fabrication, and test direction; t_c is time at soak temperature; F_{YS} is a temperature-dependent term; and

$$q = \int \frac{dt}{F_{YS}} \qquad \textbf{(Eq 6)}$$

where *t* is time during heating.

Equation 5 provides the basis for selection of a nominal aging time that will result in the desired yield strength and gives the furnace operator a method of compensating for heating rate and for differences between desired and attained soak temperatures.

Specifics will be illustrated using data for alloy 7050. The value of F_{YS} (in units of hours) for 7050 can be calculated by the following equation:

$$F_{YS} = 1.45x10^{-16} \exp\left(\frac{32562}{T_F + 460}\right) \qquad \textbf{(Eq 7a)}$$

where T_F is temperature in °F, or

$$F_{YS} = 1.45x10^{-6} \exp\left(\frac{18090}{T_k}\right) \qquad \textbf{(Eq 7b)}$$

where T_K is temperature in K.

In one experiment, lengths of 7050-W (4 days) extrusions were aged at 24 h at 120 °C (250 °F) plus the equivalent of 3 to 42 h at 165 °C (325 °F). For the second step, a logarithmic heatup was used in which 10 h were required for the load to reach 155 °C (315 °F), and nominal soak temperature was 165 °C (325 °F). Figure 24 indicates that yield strength generally agreed with values predicted using Eq 5. The deviation of the curve for short-transverse strength at the short aging times indicates that the method is inadequate for predicting strength on the underaging side of the aging curve.

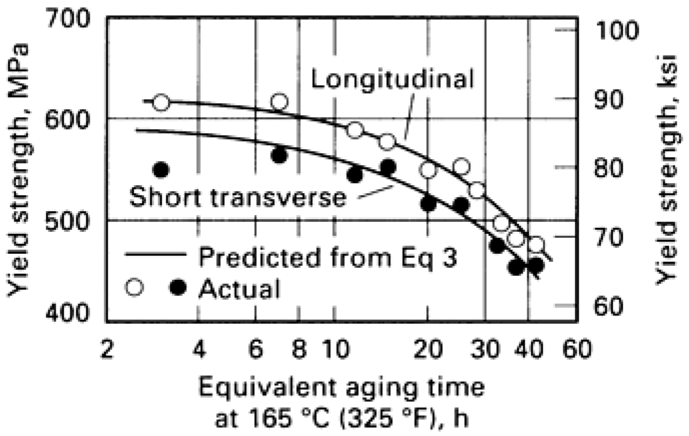

Fig. 24 Actual versus predicted yield strengths for alloy 7050 extrusions

The effects of neglecting to compensate for soaking at temperatures other than the nominal can be large (Fig. 25). For example, the calculated difference in strength between alloy 7050 extrusions soaked 29 h at 160 °C (320 °F) and at 165 °C (325 °F) is about 50 MPa (7 ksi), and the calculated difference in strength between 7050 extrusions soaked 29 h at 155 °C (315 °F) and at 170 °C (335 °F) is about 100 MPa (14 ksi).

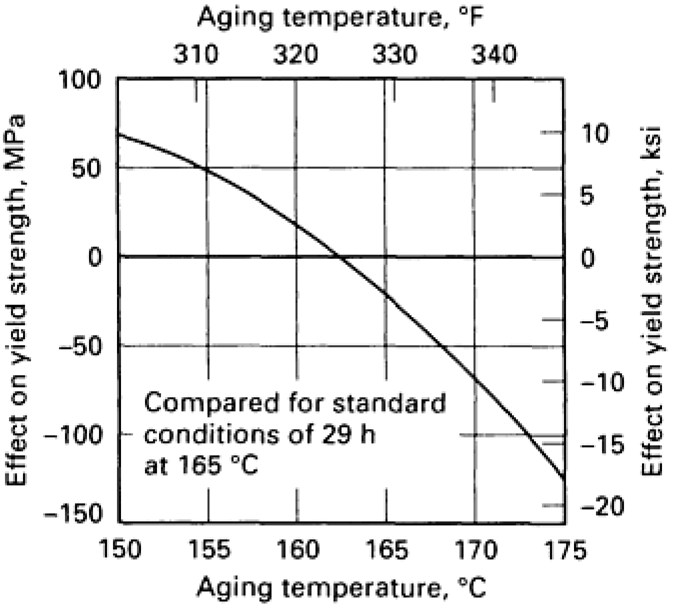

Fig. 25 Effect of aging temperature on yield strength of alloy 7050-T736

Neglecting to compensate for time spent heating the work to the soak temperature will increase the variability. Strength loss attributed to heatup was 14 MPa (2 ksi).

These kinetic relationships also can assist in selection of equivalent aging times for alternate second-step aging temperatures. Equations 5, 7a, and 7b can be rearranged to yield the following equation:

$$t_2 = t_1 \exp \frac{32562}{T_1 + 460} - \frac{32562}{T_2 + 460} \quad \textbf{(Eq 8)}$$

where t_1 is aging time at temperature T_1, t_2 is aging time at temperature T_2 that will provide equivalent yield strength, and T_1 and T_2 are in °F. For example, the time at 175 °C (350 °F) equivalent to aging alloy 7050 for 29 h at 165 °C (325 °F) is calculated as follows:

$$t_{350} = 29/\exp\ (1.28) = 29/3.6 = 8\ \text{h}$$

Thermomechanical effects on aging occur from deformation after solution heat treatment. The deformation step may be warm or cold and before, after, or during aging. The simplest thermomechanical practices are those of the conventional T3, T8, or T9 tempers. The rate and extent of precipitation strengthening are distinctly increased in some alloys by cold working after quenching, whereas other alloys show little or no added strengthening when treated by this sequence of operations.

Alloys of the 2*xxx* series such as 2014, 2124, and 2219 are particularly responsive to cold work between quenching and aging, and this characteristic is the basis for the higher-strength T8 tempers. The strength improvement accruing from the combination of cold working and precipitation heat treating is a result of nucleation of additional precipitate particles by the increased strain. In some alloys of the 2*xxx* series, strain introduced by cold working after solution heat treatment and quenching also induces nucleation of a finer precipitate dispersion that increases strength. Depending on the aging temper, however, toughness may be adversely affected, as illustrated in Fig. 26 for 2024 sheet.

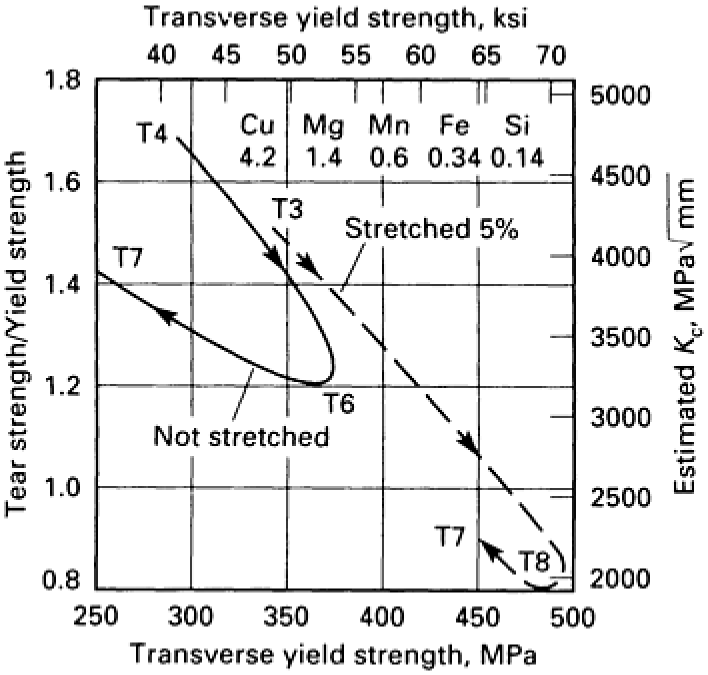

Fig. 26 Effect of stretching and aging on the toughness and yield strength of 2024 sheet

Strengthening from thermomechanical processing is the basis for the higher-strength T8-type tempers of alloys 2011, 2024, 2124, 2219, and 2419, which are produced by applying controlled amounts of cold rolling, stretching, or combinations of these operations. Normally, cold work is introduced by stretching; however, other methods such as cold rolling can be used. Recently, 2324-T39 was developed. The T39 temper is obtained by cold rolling approximately 10% after quenching followed by stretching to stress relieve. This type of approach results in strengths similar to those obtained with T8 processing but with the better toughness and fatigue characteristics of T3 products. Alloys 2024, 2124, and 2219 in T8-type tempers are particularly well suited for supersonic and military aircraft; alloy 2219 in such tempers, and alloy 2014-T65, were the principal materials for the fuel and oxidizer tanks (which also served as the primary structure) of the Saturn V space vehicles. Re-solution heat treatment of mill products supplied in these tempers can result in grain growth and in substantially lower strength than is normal for the original temper. Such reheat treatment is not recommended.

Alloys of the 7*xxx* series do not respond favorably to the sequence of operations used to produce T8-type tempers, and no such tempers are standard for these alloys. The strains associated with stretching or compressing of 7*xxx* alloys have relatively little effect on the mechanical properties of material precipitation heat treated to T6-type tempers. On the other hand, these operations have measurable detrimental effects on final strength when T73-, T736, or T76-type tempers are produced, particularly in the direction opposite the direction of cold work. Accordingly, specification properties are somewhat lower for the stress-relieved versions of these tempers. Decreasing the overaging time to compensate for the loss in strength is not advisable, because this would impair development of the desired corrosion characteristics.

Temperature control and uniformity present essentially the same problems in precipitation heat treating as they do in solution heat treating.

Good temperature control and uniformity throughout the furnace and load are required for all precipitation heat treating. Recommended temperatures are generally those that are least critical and that can be used with practical time cycles. Except for 7*xxx* alloys in T7*x* tempers, these temperatures generally allow some latitude and should have a high probability of meeting property specification requirements. Furnace radiation effects seldom are troublesome except in those few furnaces that are used for both solution and precipitation heat treating. Generally, such situations should be avoided, because the high heat capacity needed for the higher temperatures may be difficult to control at normal aging temperatures.

Soak time in precipitation heat treating is not difficult to control; the specified times carry rather broad tolerances. Heavier loads with parts racked closer together, and even nested, are not abnormal. The principal hazard is undersoaking due to gross excesses in loading practices. Some regions of the load may reach soak temperature long after soak time has been called. Placement of load thermocouples is critical, and limiting the size and spacing of a load may be necessary for aging to the T73 and T76 tempers. As discussed above, soak time is not as critical for peakaged (T6 and T8) tempers.

Hardening of Cast Alloys

In general, the principles and procedures for heat treating wrought and cast alloys are similar. The major differences between solution-treating conditions for castings and those for wrought products are found in soak times and quenching media. Solution of the relatively large microconstituents present in castings requires longer soaking periods than those used for wrought products (Table 3). When heat treatment of castings must be repeated, solution times become similar to those for wrought products, because the gross solution and homogenization has been accomplished and is irreversible under normal conditions. Reduction of stresses and distortion from quenching are also important, because castings generally are complex shapes with variations in section thickness.

Different casting processes and foundry practices also result in microstructural differences with relevance to heat-treatment practice, because the coarser microstructures associated with slow solidification rates require a longer solution heat treatment exposure. Therefore, the time required at temperature to achieve solution is progressively shorter for investment, sand, and permanent mold castings. Foundry practice (chills, gating, type of mold) also plays an important role in the response of a casting, or a portion of a casting, to heat treatment. For example, thin-wall sand castings produced with extensive use of chills can often display finer microstructures than heavy-section permanent mold parts produced in such a way that process advantages are not exploited.

For these reasons, solution heat-treatment practices can be optimized for any specific part to achieve solution with the shortest reasonable cycle once production practice is finalized, even though most foundries and heat treaters will standardize a practice with a large margin of safety. There also exists a fundamental difference between unmodified and modified alloys in which the size and shape of silicon crystals are modified with additions of elements such as calcium, sodium, strontium, or antimony. Modified alloys undergo rapid spheroidization while complete spheroidization is not achieved in unmodified alloys even after very long times. The practical implication is that shorter solution heat treatment could be employed in fully modified castings. The microsegregation of silicon and magnesium is not severe in the aluminum-silicon-magnesium casting alloys, and hence it takes only a short time to homogenize the alloy and to place the Mg_2Si into solution.

Quenchants. Quenching of aluminum castings is often done in boiling water or a milder medium to reduce quenching stresses in complex shapes. A commercially important variety is a mixture of polyalkylene glycol and water, which has no detrimental effect on properties for thicknesses under approximately 3.2 mm (0.125 in.). Quenchant additions can be made for the following purposes:

- To promote stable vapor film boiling by the deposition of compounds on the surface of parts as they are submerged in the quench solution
- To suppress variations in heat flux by increasing vapor film boiling stability through chemically decreased quench solution surface tension
- To moderate quench rate for a given water temperature

The key to the compromise between goals involving property development and the physical consequences of quenching is uniformity of heat extraction, which is in turn a complex function of the operable heat extraction mechanism. Nucleate, vapor film, and convective boiling occur with dramatically different heat extraction rates at different intervals. Differences in section thickness, load density, positioning, racking methods, surface condition, and casting geometry also influence the results.

Property Development. Yield strength is largely controlled by the limiting hardening-element level, and tensile strength (in a general sense) is related to the ductility at a given yield strength. Ductility, however, is controlled for a given yield strength by soundness and microstructural fineness, and is thus determined in the foundry and not by the heat treater. This effect of casting methods on property development is shown in Fig. 27. Because of the finer cast structure and higher supersaturation of the more rapidly solidified permanent mold castings, their tensile properties are superior to those of sand castings of the same composition similarly heat treated.

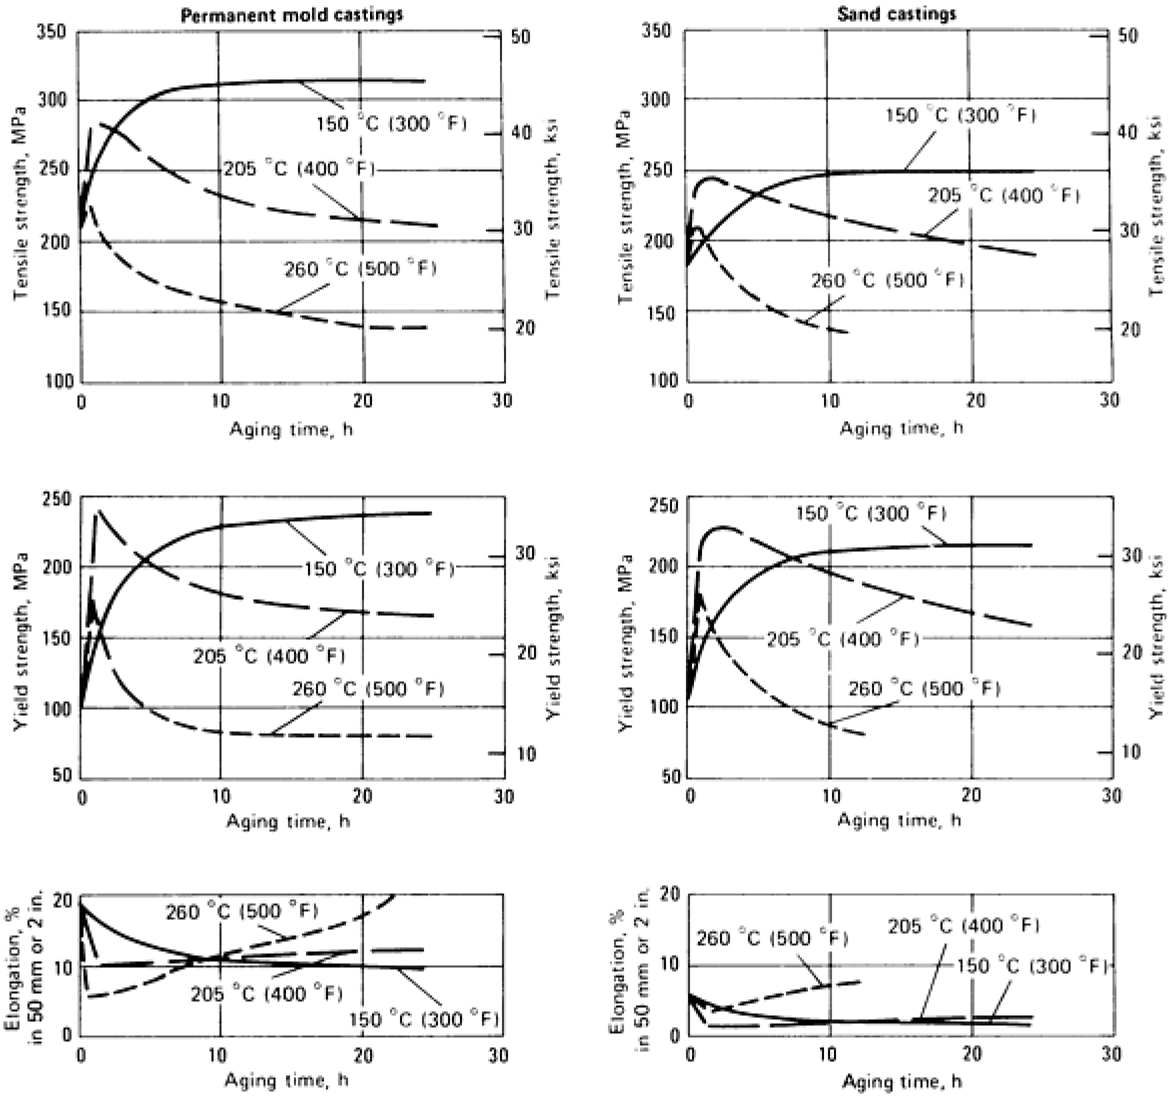

Fig. 27 Comparison of the precipitation-hardening characteristics of 356.0-T4 sand and permanent mold

castings

Tempers. Cast products of heat-treatable aluminum alloys have the highest combinations of strength, ductility, and toughness when produced in T6-type tempers. Developing T6-type tempers in cast products requires the same sequence of operations employed in developing tempers of the same type in wrought products--solution heat treating, quenching, and precipitation heat treating. Premium-quality casting specifications such as MIL-A-21180 can require different strengths and ductility levels in the same casting.

Among precipitation treatments unique to castings are those resulting in the T5 and T7 tempers. The T5 temper is produced merely by applying a precipitation treatment to the as-cast casting, without previous solution treatment. A moderate increase in strength is achieved without warpage and subsequent straightening. High hardness and dimensional and strength stability at elevated temperatures account for the almost universal use of materials in T5 tempers for pistons and other engine parts. Some applications demand combinations of strength, toughness, and dimensional stability that cannot be met by heat treating to T5-, T6-, or T8-type tempers. For these applications, T7-type tempers are developed by solution heat treating, quenching in a medium that provides a moderate cooling rate, and then precipitation heat treating at a temperature higher than those used to develop T5-, T6-, and T8-type tempers. Heat treating to T7-type tempers results in lower strength than that of material in T6- or T8-type tempers, develops high ductility and toughness, and carries precipitation far enough to minimize further precipitation during service.

Stress Relief

Immediately after being quenched, most aluminum alloys are nearly as ductile as they are in the annealed condition. Consequently, it is often advantageous to stress relieve parts by working the metal immediately after quenching. Numerous attempts also have been made to develop a thermal treatment that will remove, or appreciably reduce, quenching stresses. Normal precipitation heat-treating temperatures are generally too low to provide appreciable stress relief. Exposure to higher temperatures (at which stresses are relieved more effectively) results in lower properties. However, such treatments are sometimes utilized when even moderate reduction of residual stress levels is important enough so that some sacrifice in mechanical properties can be accepted. The T7 temper for castings is a typical example of this kind of treatment.

Mechanical Stress Relief. Deformation consists of stretching (bar, extrusions, and plate) or compressing (forgings) the product sufficiently to achieve a small but controlled amount (1 to 3%) of plastic deformation. If the benefits of mechanical stress relieving are needed, the user should refrain from reheat treating.

Figure 28 illustrates the beneficial effect of 3% permanent deformation in compression on a large forging.

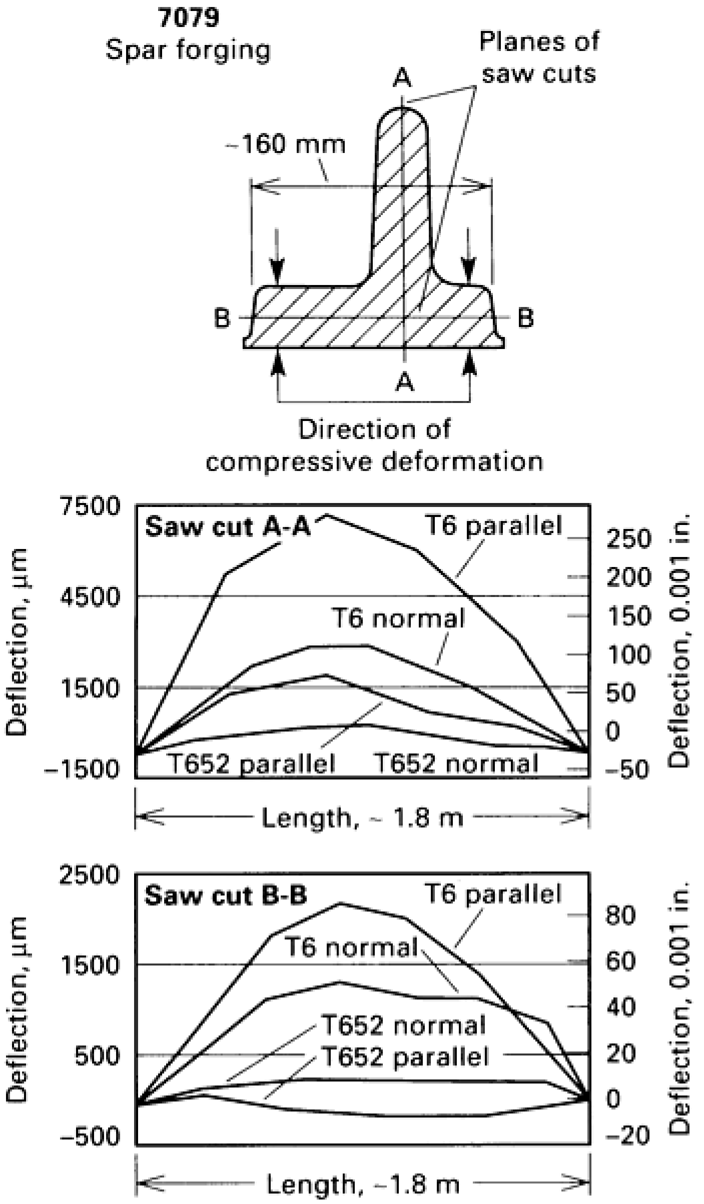

Fig. 28 Effect of 3% permanent deformation in compression (T652 treatment) on distribution of stress in a large forging. Parallel and normal refer to warpage directions with respect to the plane of the saw cut.

These methods are most readily adaptable to mill and forge shop products and require equipment of greater capacity than that found in most manufacturing plants. Application of these methods to die forgings and extrusions usually requires construction of special dies and jaws. Stretching generally is limited to material of uniform cross section; however, it has been applied successfully to stepped extrusions and to a 3 by 14 m (10 by 47 ft) aircraft wing skin roll-tapered to a thickness range of 7.1 to 3.2 mm (0.280 to 0.125 in.).

Specific combinations of the supplemental digits are used to denote the tempers produced when mechanical deformation is used primarily to relieve residual stresses induced during the quenching operation. For products stress relieved by stretching, the digits 51 follow the basic T*x* designation (T451, for example). For products stress relieved by compressive deformation, the supplementary digits are 52.

An additional digit is added to designations for extrusions: an added zero specifies that the product has not been straightened after final stretching; an added one indicates that straightening may have been performed after final stretching.

Effect of Precipitation Heat Treating on Residual Stress. The stresses developed during quenching from solution heat treatment are reduced during subsequent precipitation heat treatment. The degree of relaxation of stresses is highly dependent upon the time and temperature of the precipitation treatment and the alloy composition. In general, the precipitation treatments used to obtain the T6 tempers provide only modest reduction in stresses, ranging from about 10 to 35%. To achieve a substantial lowering of quenching stresses by thermal stress relaxation, higher-temperature treatments of the T7 type are required. These treatments are used when the lower strengths resulting from overaging are acceptable.

Other thermal stress-relief treatments, known as subzero treatment and cold stabilization, involve cycling of parts above and below room temperature. The temperatures chosen are those that can be readily obtained with boiling water and mixtures of dry ice and alcohol--namely, 100 and -73 °C (212 and -100 °F)--and the number of cycles ranges from one to five. The maximum reduction in residual stress that can be effected by these techniques is about 25%. The maximum effect can be obtained only if the subzero step is performed first, and immediately after quenching from the solution-treating temperature while yield strength is low. No benefit is gained from more than one cycle.

A 25% reduction in residual stress is sometimes sufficient to permit fabrication of a part that could not be made without this reduction. However, if a general reduction is needed, as much as 83% relief of residual stress is possible by increasing the severity of the uphill quench--that is, more closely approximating the reverse of the coolingrate differential during the original quench. This may be accomplished by a patented process that involves extending the subzero step to -195 °C (-320 °F) and then very rapidly uphill quenching in a blast of live steam (Fig. 29). The rate of reheating is extremely critical, and therefore, to ensure proper application of the steam blast, a special fixture usually is required for each part.

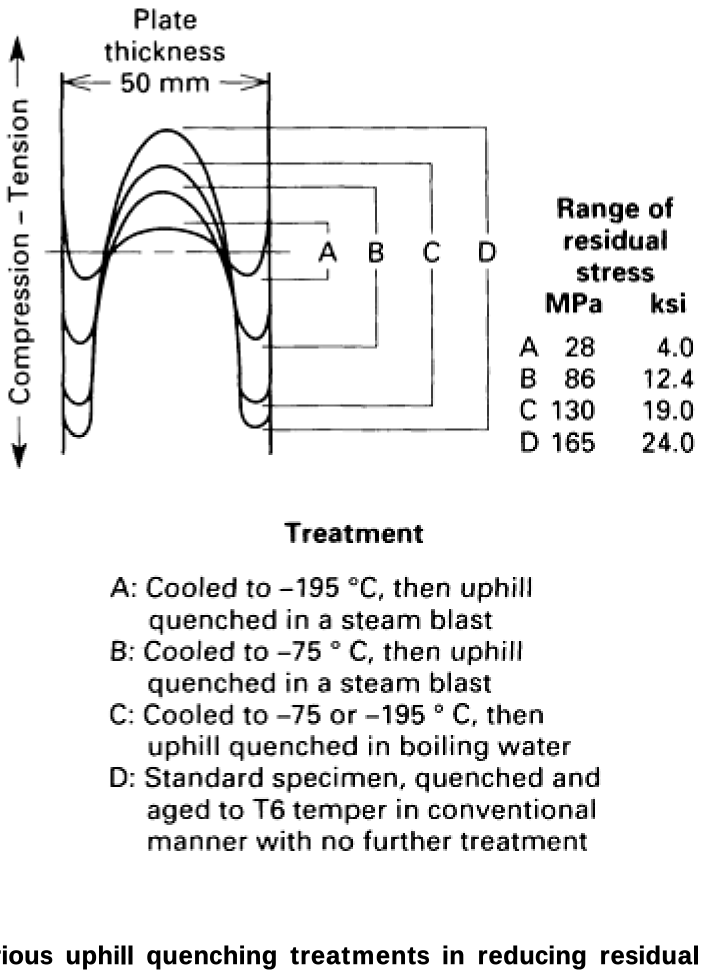

Fig. 29 Effectiveness of various uphill quenching treatments in reducing residual quenching stresses in 2014 plate. Note: uphill quenching treatments (single-cycle only) were applied from $\frac{1}{2}$ to $1\frac{1}{2}$ h after quenching from the recommended solution-treating temperature. All specimens were aged to the T6 temper after uphill quenching.

This process will not solve all problems of warpage in machining. It may reduce warpage internally but increase warpage of the extreme outer layers, although in the opposite direction (Fig. 30). Also, the effect of the altered residual-stress pattern on performance must be evaluated carefully for each part. This is particularly important for parts subjected to cyclic loading or exposed to corrosive environments such as marine atmospheres, especially if the process is introduced after the start of production and original performance tests are not repeated. Further disadvantages are the cost and hazard involved in handling liquid nitrogen and live steam.

Effects of Reheating

The precipitation characteristics of aluminum alloys must be considered frequently during evaluation of the effects of reheating on mechanical properties and corrosion resistance. Such evaluations are necessary for determining standard practices for manufacturing operations, such as hot forming and straightening, adhesive bonding, and paint and dry-film lubricant curing, and for evaluating the effects of both short-term and long-term exposure in elevated temperatures in service.

The stage of precipitation that exists in an alloy at the time of reheating plays a significant role in the effects of reheating. Consequently, it is extremely dangerous to reheat material in a solution heat-treated temper without first carefully testing the effects of such reheating. In one such test, 2024-T4 sheet was found to be very susceptible to intergranular corrosion when subjected to a 15-min drying operation at 150 °C (300 °F) during the first 8 h after quenching; no susceptibility was evident when the same drying operation was performed more than 16 h after quenching. In another test, 7075-W (0.2 to 600 h) bar and plate were reheated for hot forming at 175 °C (350 °F) for 20 min. Strengths after aging to the T6 temper were 10 to 15% lower than those for standard 7075-T6. In contrast, similar reheating of T6 material for up to 1 h at 175 °C (350 °F) produced no detrimental effect.

If reheating is performed on material in the W or T4 condition, its effect can be estimated from families of precipitation heat-treating curves such as those presented in Fig. 22(a), 22(b), 22(c), and 22(d). Such curves can also be used for reheating of precipitation heat-treated material at the precipitation heat-treating temperature. For reheating at other temperatures, other data may be needed (Fig. 31). The heat-treating and reheating curves may be used as the bases for limitations on reheating (Table 9).

Table 9 Reheating schedules for wrought aluminum alloys

The schedules given in this table normally will not decrease strength more than 5%.

Annealing

Annealing treatments employed for aluminum alloys are of several types that differ in objective. Annealing times and temperatures depend on alloy type as well as on initial structure and temper.

Full Annealing. The softest, most ductile, and most workable condition of both non-heat-treatable and heat-treatable wrought alloys is produced by full annealing to the temper designated "O." Strain-hardened products in this temper normally become recrystallized, but hot-worked products may remain unrecrystallized. In the case of heat-treatable alloys, the solutes are sufficiently thoroughly precipitated to prevent natural age hardening. A higher maximum temperature than that used for stress-relief annealing, controlled cooling to a lower temperature, and additional holding time at the lower temperature generally are employed.

For both heat-treatable and non-heat-treatable aluminum alloys, reduction or elimination of the strengthening effects of cold working is accomplished by heating at a temperature from about 260 to about 440 °C (500 to 825 °F). The rate of softening is strongly temperature-dependent; the time required to soften a given material by a given amount can vary from hours at low temperatures to seconds at high temperatures.

If the purpose of annealing is merely to remove the effects of strain hardening, heating to about 345 °C (650 °F) will usually suffice. If it is necessary to remove the hardening effects of a heat treatment or of cooling from hot-working temperatures, a treatment designed to produce a coarse, widely spaced precipitate is employed. This usually consists of soaking at 415 to 440 °C (775 to 825 °F) followed by slow cooling (28 °C/h, or 50 °F/h, max) to about 260 °C (500 °F). The high diffusion rates that exist during soaking and slow cooling permit maximum coalescence of precipitate particles and result in minimum hardness.

As a result of this treatment, only partial precipitation occurs in 7*xxx* alloys, and a second treatment (soaking at 230 ±6 °C, or 450 ± 10 °F, for 2 h) is required. When the need arises for small additional improvements in formability, cooling at 28 °C/h (50 °F/h) should be extended to 230 °C (450 °F), and the material should be soaked at 230 °C for 6 h. The effects of eliminating or prolonging the 230 °C second step on the ductility of 7075-O sheet are compared with the standard treatment in Table 10.

Table 10 Effects of annealing treatments on ductility of 7075-O sheet

(b) Bend angle at first fracture.

(c) Elongation in bend test for 1.3 mm (0.05 in.) gage spanning fracture.

(d) Soak 2 h at 415 ± 14 °C (775 ± 25 °F); furnace cool to 260 °C (500 °F) at 30 °C/h (50 °F/h); air cool.

(e) Soak 2 h at 425 °C (800 °F), air cool; soak 2 h at 230 °C (450 °F), air cool.

(f) Soak 1 h at 425 °C (800 °F); furnace cool to 230 °C (450 °F) at 30 °C/h (50 °F/h); soak 6 h at 230 °C (450 °F), air cool

In annealing, it is important to ensure that the proper temperature is reached in all portions of the load; therefore, it is common to specify a soaking period of at least 1 h. The maximum annealing temperature is moderately critical; it is advisable not to exceed 415 °C (775 °F), because of oxidation and grain growth. The heating rate can be critical, especially for alloy 3003, which usually requires rapid heating for prevention of grain growth. Relatively slow cooling, in still air or in the furnace, is recommended for all alloys to minimize distortion. Typical annealing conditions used for some alloys in common use are listed in Table 11.

Table 11 Typical full annealing treatments for some common wrought aluminum alloys

These treatments, which anneal the material to the O temper, are typical for various sizes and methods of manufacture and may not exactly describe optimum treatments for specific items.

(a) Time in the furnace need not be longer than necessary to bring all parts of the load to appealing temperature. Cooling rate is unimportant.

(b) These treatments are intended to remove the effects of solution treatment and include cooling at a rate of about 30 °C/h (50 °F/h) from the annealing temperature to 260 °C (500 °F). Rate of subsequent cooling is unimportant. Treatment at 345 °C (650 °F), followed by uncontrolled cooling, may be used to remove the effects of cold work or to partly remove the effects of heat treatment.

(c) These treatments are intended to remove the effects of solution treatment and include cooling at an uncontrolled rate to 205 °C (400 °F) or less, followed by reheating to 230 °C (450 °F) for 4 h. Treatment at 345 °C (650 °F), followed by uncontrolled cooling, may be used to remove the effects of cold work or to partly remove the effects of heat treatment.

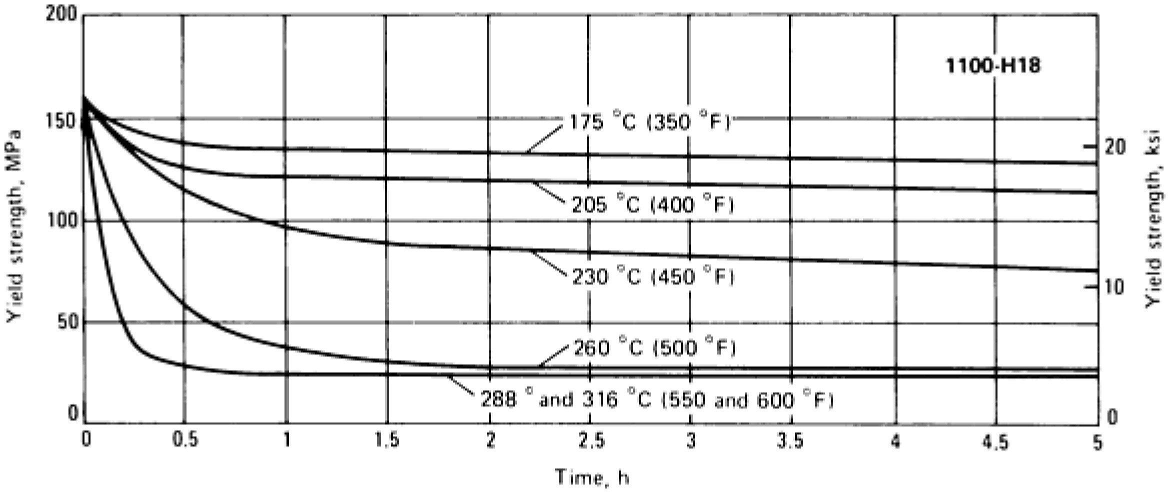
(d) Cooling rate to 205 °C (400 °F) or below is less than or equal to 30 °C/h (50 °F/h).

Products that can be heated and cooled very rapidly, such as wire, are annealed by continuous processes that require a total heating and cooling time of only a few seconds. Continuous annealing of coiled sheet is accomplished in a total time of a few minutes. For these extremely rapid operations, maximum temperature may exceed 440 °C (825 °F).

Although material annealed from the precipitation-hardened condition usually has sufficient ductility for most forming operations, this ductility often is slightly lower than that of material that has not been subjected to prior heat treatment--that is, material annealed at the producing source. Therefore, when maximum ductility is required, annealing of a previously heat-treated product is sometimes unsuccessful.

Partial Annealing. Annealing of cold-worked non-heat-treatable wrought alloys to obtain intermediate mechanical properties (H2-type tempers) is referred to as partial annealing or recovery annealing. Temperatures used are below those that produce extensive recrystallization, and incomplete softening is accomplished by substructural changes in dislocation density and rearrangement into cellular patterns (polygonization). Bendability and formability of an alloy annealed to an H2-type temper generally are significantly higher than those of the same alloy in which an equal strength level is developed by a final cold-working operation (H1-type temper). Treatments to produce H2-type tempers require close control of temperature to achieve uniform and consistent mechanical properties.

Figure 32 shows changes in yield strength as functions of temperature and time for sheet of two non-heat-treatable alloys (1100 and 5052) initially in the highly cold-worked condition (H18 temper). From these curves, it is apparent that, by selection of appropriate combinations of time and temperature, mechanical properties intermediate to those of cold-worked and fully annealed material can be obtained. It is also evident that yield strength depends much more strongly on temperature than on time of heating.



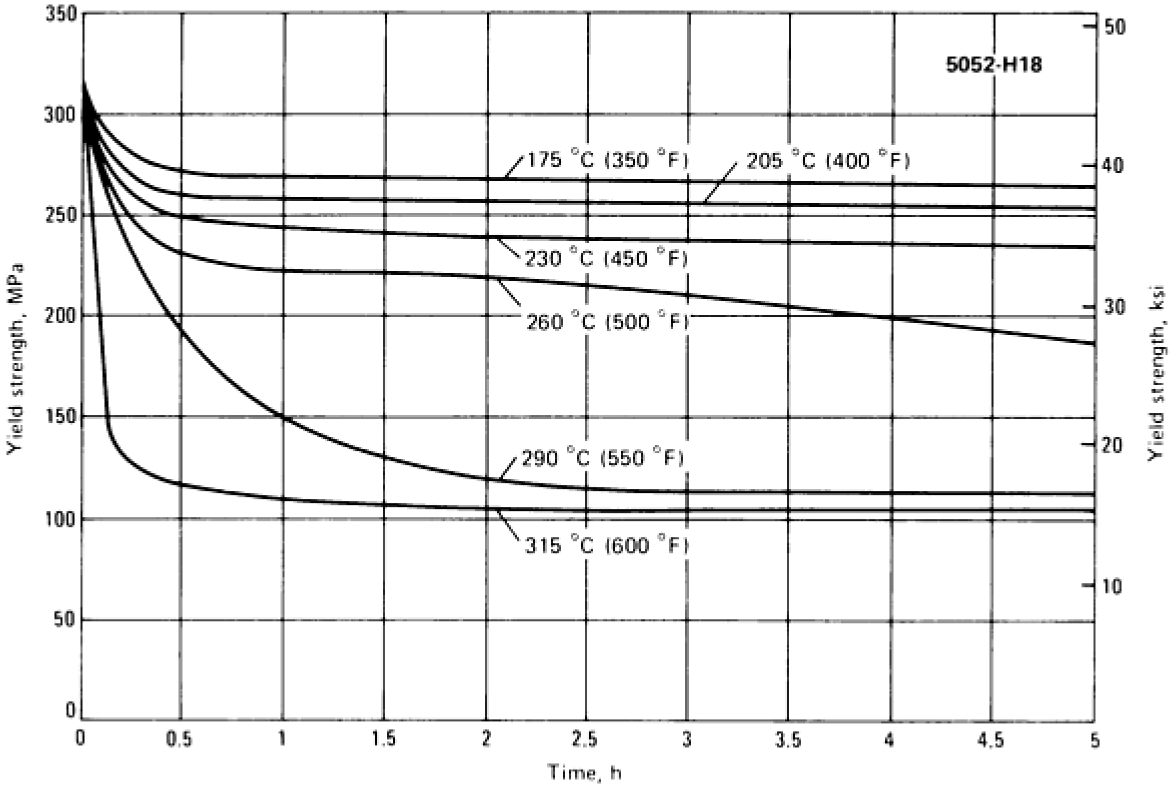


Fig. 32 Representative isothermal annealing curves for alloys 1100-H18 and 5052-H18

Stress-Relief Annealing. For cold-worked wrought alloys, annealing merely to remove the effects of strain hardening is referred to as stress-relief annealing. Such treatments employ temperatures up to about 345 °C (650 °F), or up to 400 ± 8 °C (750 ± 15 °F) for 3003 alloy, and cooling to room temperature. No appreciable holding time is required. Such treatment may result in simple recovery, partial recrystallization, or full recrystallization. Age hardening may follow stress-relief annealing of heat-treatable alloys, however, because a concentration of soluble alloying elements sufficient to cause natural aging remains in solid solution after such treatments.

A special form of stress-relief temper is used for heat-treatable alloy products that subsequently will be inspected ultrasonically. The product is heated to its normal solution heat-treating temperature, then cooled in still air to room temperature. This temper is referred to as the O1 temper.

Controlled-Atmosphere Annealing and Stabilizing. Aluminum alloys that contain even very small amounts of magnesium will form a surface magnesium oxide unless the atmosphere in the annealing furnace is free of moisture and oxygen. Examples include alloy 3004, which is used for cooking utensils, and alloys of the 5*xxx* series.

Another problem that control of the annealing atmosphere helps to overcome or avoid is oil staining by oil-base roll lubricants that do not burn off at lower annealing temperatures. If the oxygen content of the furnace atmosphere is kept very low during such annealing, the oil will not oxidize and stain the work.

Temperature control for full and partial annealing is somewhat more critical than for stress-relief annealing; the temperatures and times specified are selected to produce recrystallization and, in the case of heat-treatable alloys, a precipitate of maximum size; for this the cooling rate must be closely controlled. Even allowing the load to cool in the furnace may result in an excessively high rate. Similarly, lowering the furnace-control instrument by 28 °C (50 °F) each hour may produce stepped cooling, which is not satisfactory for severe forming operations. For maximum softening, a continuous cooling rate of not more than 28 °C/h (50 °F/h) is recommended.

Annealing of castings for 2 to 4 h at temperatures from 315 to 345 °C (600 to 650 °F) provides the most complete relief of residual stresses and precipitation of the phases formed by the excess solute retained in solid solution in the as-cast condition. Such annealing treatments provide maximum dimensional stability for service at elevated temperatures. The annealed temper is designated "O." (This temper was designated "T2" prior to 1975.)

Grain Growth

Many of the aluminum alloys in common use are subject to grain growth during solution treatment or annealing. This phenomenon can occur during or after recrystallization of material that has been subjected to a small critical amount of prior cold work. It is usually manifested by surface roughening during subsequent fabrication operations and frequently results in rejections for appearance or functional reasons. Less frequently, some deterioration of mechanical properties is encountered, and this is undesirable regardless of surface-roughening effects.

Degree of susceptibility to grain growth varies with alloy, structure, and chemical-composition variation, and from one product form to another. The critical range of cold work is ordinarily about 5 to 15%. Usually, temperatures of 400 °C (750 °F) and above must be reached before grain growth occurs, but some growth has been encountered at temperatures as low as 345 °C (650 °F). Grain growth that occurs during initial recrystallization is more a function of composition, structure, and degree of cold work than of temperature per se; temperatures in excess of 455 °C (850 °F) in common alloys can lead to secondary-recrystallization grain-growth problems. The common symptom indicating moderately large-grain material is roughening or "orange peel" on the external surfaces of bends. Severe growth of grains to fingernail size and larger sometimes is evident in parts made from annealed (O temper) material by stretch forming and then thermal treating or similar operations. This type of grain growth often is detected during subsequent anodizing, etching, and chemical milling operations.

Cracking during welding or brazing is another characteristic which may indicate that severe grain growth has occurred. In such instances, cracks propagate along grain boundaries that provide little obstruction to their progress.

If the surface roughening is objectionable from either an appearance or a functional aspect, the desirability of surface-smoothing operations, such as sanding or buffing, must be evaluated. If reductions in mechanical properties are suspected, these must be established by test and evaluated in relation to the anticipated service.

In one application, a part that had been made by stretch forming O-temper 2 mm (0.080 in.) sheet and heat treating exhibited significantly lower tensile and yield strengths in portions where severe grain growth had occurred than in portions having normal grain size:

Test	Grain structure	Tensile strength	Yield strength

	structure	MPa	ksi	MPa	ksi
Transverse					
1	Coarse	265	38.5	247	**35.8**
2	Coarse	263	38.2	241	**35.0**
3	Fine	311	45.1	261	**37.8**
Longitudinal					
1	Coarse	259	37.6	243	**35.3**
2	Coarse	269	39.0	245	**35.6**
3	**Fine**	**305**	**44.2**	**270**	**39.1**

In other similar investigations, no detrimental effects have been discovered, and in many cases such parts have served satisfactorily in critical applications.

When a grain-growth problem is discovered, it is too late to change the condition of the parts in question, but several possible methods are available for preventing recurrence of the difficulty. The simplest of these is relieving the causative stress by interjecting a stress-relief anneal into the manufacturing sequence immediately prior to the solution-treating or full-annealing cycle in which the grain growth occurred. This approach is usually successful and practical. Another possibility is to adjust the amount of stress present in the part immediately prior to the critical heat treatment so that the stress level is outside the critical range. This may be done by adding a cold-working operation before forming, such as pre-stretching of blanks, or by forming in multiple stages with a stress-relief anneal before each stage.

A third method that is sometimes successful consists of increasing the heating rate during the critical heat treatment by reducing the size of furnace loads or by changing from an air furnace to a salt bath. In one application, severe grain growth was found during bending of alloy 1100 rectangular tubing. The roughening of the inside surfaces of the parts, which occurred during forming of the large-grain material, impaired their functioning as radar waveguides. Investigation disclosed that, to minimize handling marks, the material was procured in the strain-hardened (H14) temper and was stress-relief annealed at 345 °C (650 °F) immediately prior to forming. Grain growth occurred during annealing as a result of the moderate amount of cold work introduced at the mill. The problem was eliminated by changing the stress-relieving operation to a 5-min heating period in an air furnace operating at 540 °C (1000 °F). The explanation advanced for the success of this treatment was that, due to the rapid heating rate, the temperature of the material was raised through the recrystallization range for the less severely cold-worked grains before the critically cold-worked grains had time to grow appreciably.

Heating Equipment and Accessories

The general methods for heat treating aluminum alloys include the use of molten salt baths, air-chamber furnaces, and induction heaters. The choice of heating equipment depends largely on the alloy and the configuration of the parts to be processed. The type of heat treatment can also influence the choice of heating equipment. For example, both molten salt baths and air-chamber furnaces are suitable for solution treating of aluminum alloys, while induction heating requires additional analysis to define the proper temperature range for solution treatment. Induction methods can provide high heating rates, which affect transformation behavior (see, for example, the section "Nonequilibrium Melting" in this article).

Molten salt baths and air-chamber furnaces both have advantages and disadvantages in solution heat treatments, as discussed below. Oil- and gas-fired furnaces, in designs that allow the products of combustion to come in contact with the work, are usually unsatisfactory because they promote high-temperature oxidation.

Salt baths heat the work faster (see Table 2) than air furnaces, provided that the amount of work introduced at any one time is controlled to prevent the temperature from falling below the desired range. If the temperature is permitted to fall below the minimum limit, much of the advantage of the salt bath is lost, because of the necessity for reheating the large mass of salt.

Salt baths are also more readily adapted to the introduction, at any time, of small amounts of work requiring different soaking periods. (Economical utilization of air furnaces usually dictates accumulation of a large load of parts of similar thickness before charging.) Also, the buoyant effect of the salt reduces distortion during heating, and the large reservoir of heat facilitates temperature control and uniformity.

Salt bath operation entails special house-keeping requirements. Dragout is costly and unsightly. Because residual salt on parts may result in corrosion, all salt must be completely removed, including that from crevices and blind holes. In addition, salt residue from the quench water must be kept to a minimum by a constant water overflow or by providing a fresh-water rinse for all parts after quenching. When these provisions are impractical, corrosion can be inhibited by adding 14 g ($\frac{1}{2}$ oz) of sodium or potassium dichromate to each 45 kg (100 lb) of the molten salt.

Precautions. Molten salt baths are potentially hazardous and require special precautions. Operators must be protected from splashing and dripping of the hot salt. Because heated nitrates are powerful oxidizing agents, they must never by allowed to come in contact with combustibles and reducing agents, such as magnesium and cyanides. Most authorities advise against inserting aluminum alloys containing more than a few percent of magnesium into molten nitrate. To avoid exposure of personnel to nitrous fumes produced during decomposition of nitrates, good ventilation is essential.

When molten nitrates are being used, the possibilities of explosions resulting from both physical and chemical reactions must be avoided. The former result from rapid expansion of gases entrapped beneath the surface of the bath. Hence, parts entering the bath must be clean and dry; they must also be free of pockets or cavities that contain air or other gases. Chemical-reaction explosions result from rapid breakdown of the nitrates due to overheating or reaction with the pot material. Stainless steel pots (preferably of type 321 or 347) are more resistant to scaling than those made of carbon steel or cast iron and therefore present a lower probability of local overheating. Sludge or sediment accumulations in bottom-heated pots can also lead to local overheating. Overheat controls are essential to ensure against temperatures exceeding 595 °C (1100 °F).

It is vitally important that water be kept away from a nitrate tank. In controlling a nitrate fire, do not use water or any fire extinguisher containing water. The best extinguisher is dry sand, a supply of which should be kept near the tank.

Extra sacks of salt should be stored in a dry place, distant from the tank. If the fresh salt being added to the bath is even slightly damp, it should be added very slowly or when the bath is frozen.

Air furnaces are used more widely than salt baths because they permit greater flexibility in operating temperature. When production schedules and the variety of alloys requiring heat treatment necessitate frequent changes in temperature, the time and cost of adjusting the temperature of a large mass of salt makes the use of an air furnace almost mandatory. However, waiting periods are often required to allow the walls of air furnaces to stabilize at the new temperature before parts are introduced. Otherwise, parts may radiate heat to colder walls or absorb radiant heat from hotter walls, and the temperature indicated by the control instrument will not reflect actual metal temperature in the usual manner. Air furnaces are also more economical when the product mix includes a few rather large parts; holding the temperature of a large volume of salt in readiness for an occasional large part is far more expensive than heating an equal volume of air.

Induction heating with either solenoid (longitudinal-flux) coils or transverse-flux coils provides an efficient method for in-line heating of flat-rolled products (particularly strip). Solenoid coils create a longitudinal flux, which can produce efficient heating for thicker and/or lower resistivity materials. Solenoid coils can also be used efficiently in the heating of thinner magnetic material (see, for example, steel below the Curie temperature in Table 12).

Table 12 Frequency selection for induction heating with a longitudinal-flux coil and a transverse-flux coil

Material	Minimum part thickness, mm (in.), for a frequency of:				
	60 Hz	**200 Hz**	**1 kHz**	**3 kHz**	10 kHz
Solenoid (longitudinal-flux) coil					
Steel below Curie temperature	>38 (1.5)	13 (0.5)	5 (0.2)	2.3 (0.09)	**1 (0.04)**
Steel above Curie temperature	>175 (7.0)	100 (4.0)	43 (1.7)	25 (1.0)	**13 (0.5)**
Brass	>50 (2.0)	28 (1.1)	13 (0.5)	7 (0.28)	**4 (0.16)**
Aluminum	>38 (1.5)	22 (0.85)	9 (0.375)	5 (0.2)	**3 (0.12)**
Transverse-flux coil					
Aluminum	>5 (0.2)	1.3 (0.05)	0.25 (0.01)	0.08 (0.003)	**0.04 (0.0016)**
Brass	>10 (0.4)	2.5 (0.1)	0.5 (0.02)	0.15 (0.006)	**0.08 (0.0032)**
Steel	**>50 (2.0)**	**13 (0.5)**	**2.5 (0. 1)**	**0.9 (0.035)**	**0.5 (0.020)**

For several nonferrous materials (aluminum, copper, brass), however, efficiency and power factors with solenoid coils are significantly lower than for ferrous materials. Therefore, transverse-flux coils are ideally suited for heating nonferrous materials, because transverse-flux lines do not exhibit the degree of current cancellation associated with longitudinal flux lines. This aspect of transverse-flux coils improves efficiency and also permits the use of lower frequencies (Table 12). This reduces the capital equipment costs, and where it shifts from requiring RF frequencies, the power source conversion efficiency is also significantly improved. Aluminum, brass, copper, and austenitic stainless steel strip lines are ideally suited for transverse-flux heating. Each of these materials often requires in-line processes like partial or full annealing or solution heat treating to provide necessary mechanical properties for subsequent finishing operations.

Transverse-flux induction heating offers several benefits for in-line strip heating and has been known for many years. However, it requires specially designed iron-cored laminated inductor coils and tighter control of the power, strip handling, and process parameters. Frequency selection is dictated by the resistivity and thickness of the material, while power requirements depend on the production rates, the specific heat, and the processing temperatures for a given material. Figure 33 shows typical power source requirements for transverse-flux heating of aluminum strip.

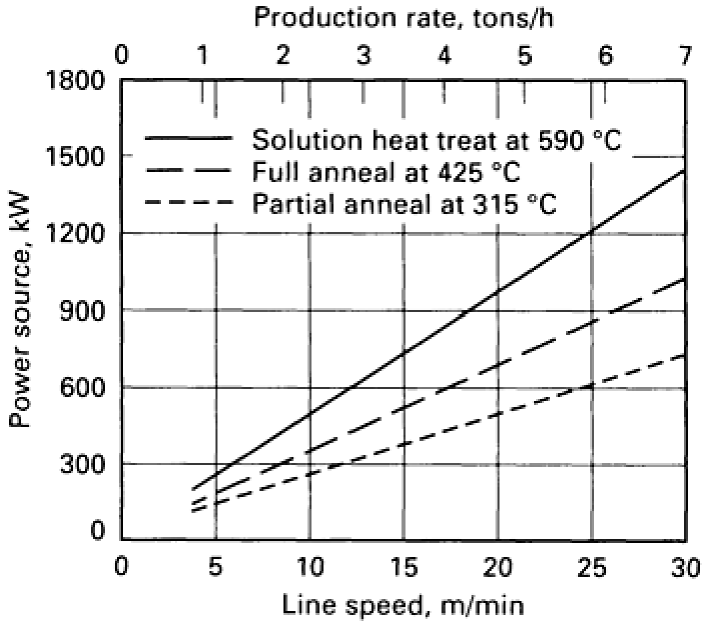

Fig. 33 Power requirement for transverse-flux induction heating of aluminum strip 1 mm (0.04 in.) thick and 1270 mm (50 in.) wide. Source: Ref 9

Furnace Temperature Control

The importance of close temperature control in solution treating has been noted in the previous section on solution treating. Each control zone of each furnace should contain at least two thermocouples. One thermocouple, with its instrument, should act as a controller, regulating the heat input; the other should act independently as a safety cutoff, requiring manual reset if its set temperature (usually the maximum of the specified range) is exceeded during the solution-treating cycle.

Safety cutoffs are mandatory for salt baths to guard against explosions and often have paid for themselves in air furnaces by saving a load of parts or even the furnace itself. It is important, however, that they be tested periodically (by deliberately overshooting the empty furnace) to guard against "frozen" corroded contacts resulting from prolonged periods of idleness.

At least one of the instruments for each zone should be of the recording type, and both instruments should have restricted scales--for instance, 400 to 600 °C (750 to 1110 °F), rather than 0 to 600 °C (32 to 1110 °F). This is required for maximum accuracy because manufacturers' guarantees are specified in terms of percent of scale.

In the placement of instruments, exposure to extremes in ambient temperature, humidity, vibration, dust, and corrosive fumes should be avoided. Ambient temperatures between 5 and 50 °C (40 and 120 °F) are satisfactory, but temperature changes of 6 °C/h (10 °F/h) or more should be avoided. It is also essential that instruments and thermocouple circuits be shielded from electromagnetic fields commonly associated with the leads of high-amperage furnace heating elements.

Temperature-sensing elements must be capable of responding more rapidly to temperature changes than the materials being processed. Therefore, thermocouple wire diameter should not exceed $1\frac{1}{2}$ times the thickness of the minimum-gage material to be heat treated, and should in no case exceed 14 gage. Thermocouples for salt baths should be enclosed in suitable protection tubes. Air-furnace thermocouples should be installed in open-end protection tubes, with the thermocouple junction extending sufficiently beyond the tube to prevent any loss in sensitivity.

Temperature-sensing elements should be located in the furnace work chamber, not in ducts and plenums, and should be as close as possible to the working zone. Specification MIL-H-6088C restricts distance between the sensing element and the working zone to a maximum of 100 mm (4 in.). The safety-cutoff thermocouple should be located to reflect the highest temperature in the working zone. The control thermocouple should be located in a position where it will read a temperature approximately halfway between the hottest and coldest temperatures.

Probe Checks. After the temperature-measurement equipment is properly installed, it must be checked frequently for accuracy. This is accomplished by inserting a calibrated probe thermocouple into the furnace adjacent to each furnace thermocouple and comparing its reading on a calibrated test potentiometer with that indicated by the furnace instrument. Correction factors should be applied after each probe check, but if the correction required exceeds ±3 °C (±5 °F), the source of the deviation should be corrected. MIL-H-6088 recommends that this check be made weekly, but many operators make the check as frequently as once each shift.

Temperature-Uniformity Surveys. In controlling the temperature of parts that are being heat treated it must first be determined that the temperature indicated by the furnace instruments truly represents the temperature of the nearby air or salt. Second, the uniformity of temperature within the working zone must be shown to be within a range of 11 °C, or 20 °F (6 °C, or 10 °F, for precipitation heat treatment of alloy 2024). This is accomplished by measuring the temperature at several test locations, using calibrated test thermocouples and a calibrated test potentiometer, and reading furnace instruments nearly simultaneously. MIL-H-6088 recommends monthly surveys with one test location per 1.1 m^3, or 40 ft^3 (0.7 m^3, or 25 ft^3, for air furnaces on initial survey), but with a minimum of nine test locations distributed as shown in Fig. 34. Despite the large size of some furnaces, rather surprising temperature uniformities have been reported. In one instance the initial survey of an air furnace measuring 12.5 by 1.2 by 3.0 m (41 by 4 by 10 ft) showed maximum temperature variations of +1.7, -1.1 °C (+3, -2 °F). When a partition 0.3 m (1 ft) thick was lowered, converting the furnace to two chambers 6.1 by 1.2 by 3.0 m (20 by 4 by 10 ft) each, the spread was +1.1, -0.6 °C (+2, -1 °F) in one section and +0.6, -1.1 °C (+1, -2 °F) in the other.

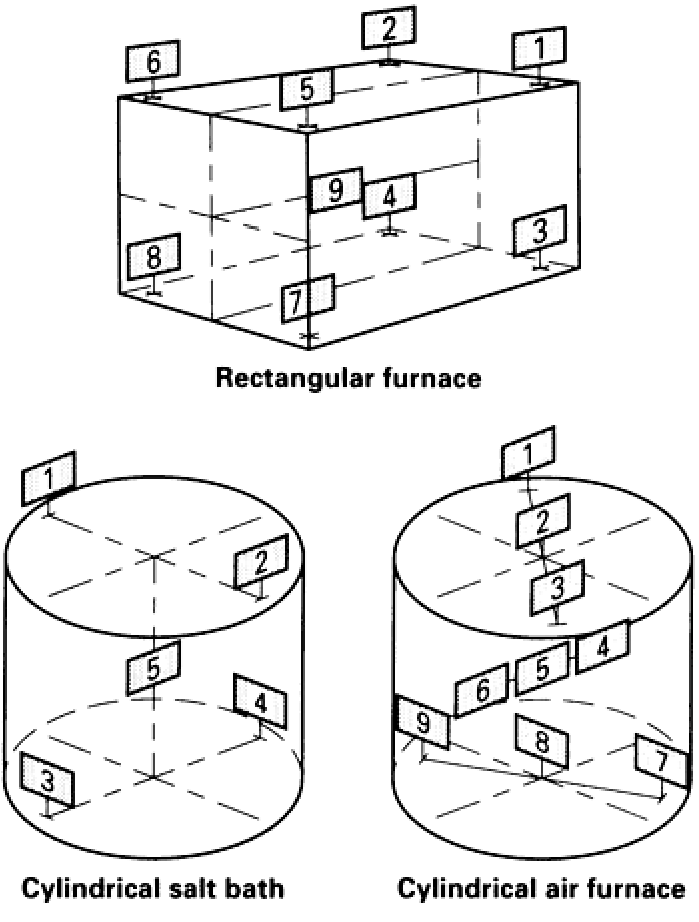

Fig. 34 Location of thermocouples for surveying temperature uniformity in the working zones of air furnaces and salt baths

For each furnace load, one thermocouple (the "cold" couple) should be placed in the coldest area of the furnace and another (the "hot" couple) in the hottest area. In addition to these two thermocouples, a load thermocouple should be installed. The load couple should be of approximately the same gage as the sheet or other product being heat treated. If heavy plate, forgings, or castings are being heat treated, a similar discarded item should be used at the controlling load couple. The thermocouple should be placed in a drilled hole and packed to hold it firmly in place during the heat-treating cycle. In some instances, the items being heat treated can be used as the load couples. The thermocouples can be placed in holes drilled in areas that will be removed in making the finished article.

It is important that items of different thicknesses--1 mm (0.040 in.) sheet and 25 mm (1 in.) plate, for example--not be heat treated in the same furnace load.

In salt baths, uniformity surveys usually are made by holding a probe thermocouple in each location until thermal equilibrium is reached; in air furnaces, a mock heat-treating cycle is required. First, the air furnace is stabilized at the test temperature. Then a rack containing the test thermocouples is inserted into the furnace. By using multiple switches or a multipoint recording instrument, all test thermocouples and furnace instruments are read every 5 min. As the temperature approaches the test range, it is advisable to increase the frequency of readings to detect possible overshooting. After thermal equilibrium is reached, readings should be continued until the recurrent temperature pattern is established.

Surveys of salt baths generally are considered acceptable whether they are made while the bath is empty or filled with work. It is controversial whether surveys of air furnaces should be made with or without a load. Undoubtedly, recovery overshoots are most likely to occur with a very light load and would not be detected if a heavier load were used. Certainly, if all loads are essentially alike, surveys should be made with typical loads. With widely varying loads, the optimum approach is to make several surveys initially, including one with an empty furnace, and then to make succeeding surveys with an empty furnace to ensure against changes in furnace characteristics. If any changes are made in the furnace that might affect temperature distribution, such as repair of vanes or louvers, several surveys should be repeated.

Another aspect of the problem of temperature control in air furnaces is the necessity of ensuring that the temperature of the parts is the same as that of the surrounding air. Furnace components whose temperature differs from the air temperature must be suitably shielded to prevent radiation to or from the parts being heat treated. In a furnace used for solution heat treating of rivets, unshielded heating elements have been known to produce part temperatures as much as 20 °C (35 °F) higher than the control temperature, resulting in eutectic melting and cracking. In two other instances, reradiation through inadequate shielding produced a radiation effect of as much as 11 °C (20 °F). One of these problems was solved by painting the shield with reflective aluminum paint and the other by adding a 13 mm ($\frac{1}{2}$ in.) thick layer of asbestos to the 1.6 mm ($\frac{1}{16}$ in.) stainless steel shield.

Furnace-wall temperatures that differ appreciably from the temperature of the parts also must be avoided. Consequently, when the operating temperature of an air furnace is changed, waiting periods are required after the furnace instrument indicates stability, to allow the furnace walls to stabilize at the new temperature. The magnitude of this limitation is directly proportional to the efficiency of the furnace as an insulated chamber, but possibilities of such radiation should be recognized even in thin-wall furnaces.

Radiation effects are potentially dangerous because they often cannot be detected by ordinary thermocouples. Specially prepared radiation panels with thermocouples attached are used, and their readings are compared with adjacent free thermocouples. These panels normally are made of material of the same gage as the thinnest parts to be heat treated and should have a single surface area of about 650 cm^2 (100 $in.^2$). A thermocouple is attached to the center of the panel by welding or peening. In order to detect the maximum effect, panel surfaces should be darkened so that their emissivity is at least as high as that of any material to be processed. During the test, the panel surfaces should be parallel to the suspected source or recipient of radiation. As an example of the number of panels required, several aerospace companies specify one panel for every 1.5 linear meters (5 linear feet) of furnace wall.

Instrument Calibration. All instruments and thermocouples must be accurately calibrated, and it is essential that the calibrations be traceable directly to the National Bureau of Standards. The chain of traceability should consist of not more than four links for sensing elements and three links for measuring elements. To illustrate, if the article calibrated by the National Bureau of Standards is called a primary standard, then the chain of traceability of measuring elements should consist of primary standard, test potentiometer, and furnace instrument. Similarly, the chain for sensing elements should consist of primary standard, secondary standard, test thermocouple, and furnace thermocouple. Every effort should be

made to ensure that the temperature indicated by the furnace instruments is as close as possible to the actual temperature. To achieve this, it is necessary to apply correction factors obtained during calibration to the next lower echelon of accuracy. Even then, if all errors inherent in the chain are in the same direction, a considerable difference will exist between the measured and actual temperatures. Therefore, it is advisable to operate as close to the mean of the desired range as possible.

Dimensional Changes during Heat Treatment

In addition to the completely reversible changes in dimensions that are simple functions of temperature change and are caused by thermal expansion and contraction, dimensional changes of more permanent character are encountered during heat treatment. These changes are of several types, some of mechanical origin and others caused by changes in metallurgical structure. Changes of mechanical origin include those arising from stresses developed by gravitational or other applied forces, from thermally induced stresses or from relaxation of residual stresses. Dimensional changes also accompany recrystallization, solution, and precipitation of alloying elements.

Solution Heat Treatment. Distortion as a result of creep during solution heat treatment should be avoided by proper loading of parts in baskets, racks, or fixtures, or by provision of adequate support for long pieces of plate, rod, bar, and extrusions heat treated in horizontal roller hearth furnaces. Sheet is provided with air-pressure support in continuous heat-treating furnaces to avoid scratching, gouging, and distortion. If parts are to be solution heat treated in fixtures or racks made of materials (such as steel) with coefficients of thermal expansion lower than that of the aluminum being treated, allowance should be made for this differential expansion to ensure that expansion of the aluminum is not restricted. Straightening immediately after solution heat treating may be preferable to fixturing.

Solution of phases formed by major alloying elements causes volumetric expansion or contraction, depending on the alloy system, and this may have to be taken into account in heat treatment of long pieces. For example, solution heat treatment and quenching of alloy 2219 causes lengthwise contraction of about 2 mm/m (0.002 in./in.). Solution heat treatment and quenching of alloys of the 7*xxx* series is accompanied by lengthwise expansion--about 0.6 mm/m (0.0006 in./in.) for alloy 7075 rod or plate.

Quenching. The most troublesome changes in dimensions and shape are those that occur during quenching or that result from stresses induced by quenching. Due to its nonuniform cooling, quenching may produce warpage or distortion, particularly in thin material and in thin sections of parts that contain variations in thickness. For thick-section products or parts, changes in external shape may be small because of rigidity, but the interior-to-surface temperature gradients that form with rapid cooling create residual stresses; these stresses normally are compressive at the surfaces and tensile in the interior.

As previously discussed, warpage or distortion of thin-section material can be reduced by using a quenching medium that provides slower cooling; however, cooling must be sufficient to produce the required properties. Slower quenching can also reduce the magnitude of residual stresses in thicker parts or pieces, as shown in Fig. 9 for cylindrical specimens of alloy 6151 quenched in cold or boiling water. Stress range (maximum tensile stress plus maximum compressive stress) for a cylinder with a radius of 89 mm (3.5 in.) is about 205 MPa (30 ksi) when the cylinder is quenched in cold water but less than 70 MPa (10 ksi) when it is quenched in boiling water. The effects of average cooling rate through the temperature range from 400 to 290 °C (750 to 550 °F) on longitudinal stress ranges developed in alloy 2014 cylinders 75 mm (3 in.) in diameter are shown in Fig. 35.

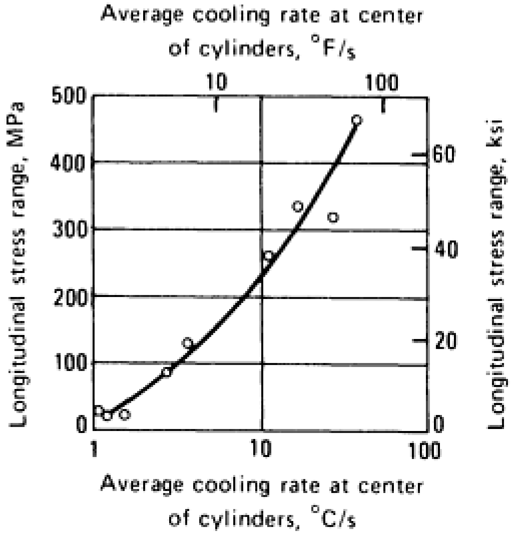

Fig. 35 Effect of quenching rate on longitudinal stress ranges in alloy 2014-T4 cylinders quenched in various media. Cylinders were 75 mm (3 in.) in diameter by 230 mm (9 in.) long. Cooling rate was measured from 400 to 290 °C (750 to 555 °F). Stress range is maximum tensile stress plus maximum compressive stress.

High stresses induced by rapid quenching generally are reduced only modestly by the precipitation heat treatments used to produce T6- or T8-type tempers. Consequently, for the alloys that require rapid cooling to develop the properties of these tempers, those incorporating mechanical stress relief (T*x*51, T*x*52) usually are specified when substantial metal must be removed to produce final shapes. Other T8-type tempers, such as T86 and T87, also have low residual stress as a result of the stretching required to produce them.

Heat Treatments for Precipitation and Stabilization. The most significant dimensional changes associated with precipitation heat treatments and stabilizing heat treatments arise from concurrent dilution of the solid solution (which changes lattice parameter) and formation of precipitate. Changes in density and specific volume resulting from these changes in metallurgical structure are the reverse of those caused by solution of the alloy phases. However, because the strongest tempers are those in which the precipitate is present in nonequilibrium transition forms, the amount of change during precipitation heat treatment does not totally compensate for the previous (and opposite) change that occurred during solution heat treatment. Most of the heat-treatable alloys expand (grow) during precipitation heat treatment. Exceptions are alloys of the 7*xxx* wrought series and the 7*xx*.0 casting series, which exhibit contraction.

In alloys of the 2*xxx* series, the amount of growth decreases with increasing magnesium content. Thus, growth of about 1.5 mm/m (0.0015 in./in.) can be expected during precipitation heat treatment of alloy 2219-T87, about 0.5 mm/m (0.005 in./in.) for treatment of alloy 2014-T6 and less than 0. 1 mm/m (0.0001 in./in.) for treatment of alloy 2024-T851. Alloys 7050 and 7075, on the other hand, contract about 0.3 mm/m (0.0003 in./in.) on precipitation heat treating from the W temper to the T6 temper and about 0.7 mm/m (0.0007 in./in.) on treating from the W temper to the T73 temper.

Stabilizing T7-type treatments cause greater amounts of growth than the T5-, T6-, or T8-type treatments for the same alloys. This increased growth is associated either with formation of increased amounts of transition precipitates or with transformation of transition precipitates to equilibrium phases.

Dimensional Stability in Service

Dimensional stability of heat-treated parts in service depends on alloy, temper, and service conditions. Of the latter, excluding mechanical conditions such as applied loads, the most important is service temperature range relative to the range in which precipitation occurs. Residual stresses constitute another source of dimensional changes. Stress relief minimizes changes due to residual stresses, and most mill products usually are supplied in tempers that include stress relief. Potential dimensional change as a result of further precipitation in parts that operate at elevated temperatures is minimized for wrought products by use of T7-type stabilizing treatments and for castings by use of T5-type treatments. However, components of high-precision equipment, such as instruments for aerospace guidance systems and optical and

telescopic devices, may require special supplementary treatments during manufacture to further reduce stresses or subsequent precipitation. (These treatments are discussed below, under "Stability of Precision Equipment.")

The T3- and T4-type tempers are the least stable dimensionally because of possible precipitation in service. Alloys 2024 and its variants have the smallest dimensional change in aging; the total change from the quenched to the average state is of the order of 0.06 mm/m (0.00006 in./in.), less than the change due to a temperature variation of 3 °C (5 °F). These alloys therefore can be used in the T3- and T4-type tempers, except for precision equipment. For all other alloys, T6- or T8-type tempers should be used, because in these tempers all the alloys have good dimensional stability.

Stability of Precision Equipment. Proper maintenance of high-precision devices, such as gyros, accelerometers, and optical systems, requires use of materials in which dimensional changes from metallurgical instability are limited from 10 μm/m (10 μin./in.). Several laboratory investigations and considerable practical experience have shown that wrought alloys 2024 and 6061 and casting alloy 356.0 are well suited and generally preferred for such applications. Dimensional changes were no greater than 10 μm/m when alloys 2024-T851 and -T62, 6061-T651 and -T62, and 356.0-T51, -T6, and -T7 were tested for more than a year at room temperature and for several months at 70 °C (160 °F), and then the same alloys were tested with repeated thermal cycling between 20 and -70 °C (68 and -94 °F).

Because stresses applied or induced by acceleration in such devices generally are not high, strength levels lower than those of the highest-strength tempers frequently are satisfactory. To increase precision of machining to intended dimensions, as well as to promote maximum stability, it is common practice to apply additional thermal treatments for stress relief and precipitation of 1 to 2 h at temperatures of 175 to 205 °C (350 to 400 °F) after rough machining. These additional treatments sometimes are repeated at successive stages of processing, and even after final machining. In addition, it has been claimed that one or two cyclic treatments consisting of cooling to -100 °C (-150 °F), holding for 2 h, heating to 232 to 240 °C (450 to 465 °F) and again holding for 2 h can improve dimensional stability of 356-T6 castings.

Quality Assurance

Quality-assurance criteria that heat-treated materials must meet always include minimum tensile properties and, for certain alloys and tempers, adequate fracture toughness and resistance to detrimental forms of corrosion (such as intergranular or exfoliation attack) or to stress-corrosion cracking. All processing steps through heat treatment must be carefully controlled to ensure high and reliable performance.

Tensile Tests. In general, the relatively constant relationships among various properties allow the use of tensile properties alone as acceptance criteria. The minimum guaranteed strength is ordinarily that value above which it has been statistically predicted with 95% probability that 99% or more of the material will pass. The inherent variability within lots and among specimens from a given piece is shown in Fig. 36. Testing provides a check for evidence of conformance; process capability and process control are the foundations for guaranteed values.

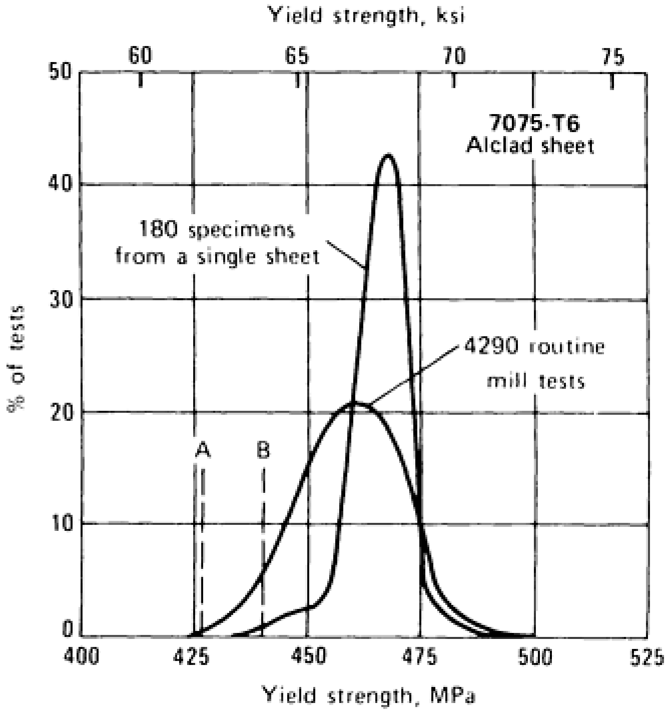

Fig. 36 Comparison of distribution of yield strength in heat-treated 7075-T6 clad sheet product with distribution in a single sheet. A is 95% probability that not more than 1% of all material will fall below this value; B is 95% probability that not more than 10% of all material will fall below this value. (A and B refer only to curve representing 4290 routine mill tests.)

Published minimum guaranteed values are applicable only to specimens cut from a specific location in the product, with their axes oriented at a specific angle to the direction of working as defined in the applicable procurement specification. In thick plate, for example, the guaranteed values apply to specimens taken from a plane midway between the center and the surface, and their axes parallel to the width dimension (long transverse). Different properties should be expected in specimens taken from other locations, or in specimens whose axes were parallel to thickness dimension (short transverse). However, the specified "referee" locations and orientations do provide a useful basis for lot-to-lot comparisons, and constitute a valuable adjunct to other process-control measures.

Tensile tests can be used to evaluate the effects of changes in the process, provided specimens are carefully selected. A variation in process that produces above-minimum properties on test specimens, however, is not necessarily satisfactory. Its acceptability can be judged only by comparing the resulting properties with those developed by the standard process on similarly located specimens. Finally, variations in heat-treating procedure are likely to affect the relationships among tensile properties and other mechanical properties. In applications where other properties are more important than tensile properties, the other properties should be checked also.

Hardness tests are less valuable for acceptance and rejection of heat-treated aluminum alloys than they are for steel. Nevertheless, hardness tests have some utility for process control. Typical hardness values for various alloys and tempers are given in Table 13. Figure 37 shows the general relationship between longitudinal tensile strength and hardness for aluminum alloys.

Table 13 Typical acceptable hardness values for wrought aluminum alloys

Acceptable hardness does not guarantee acceptable properties; acceptance should be based on acceptable hardness plus written evidence of compliance with specified heat-treating procedures. Hardness values higher than the listed maximums are acceptable provided that the material is positively identified as the correct alloy.

Intergranular-Corrosion Test. The extent of precipitation during elevated-temperature aging of alloys 2014, 2219, and 2024 markedly influences the type of corrosion attack and the corrosion resistance. With thin-section products quenched at rates sufficiently rapid to prevent precipitation in the grain boundaries during the quench, short periods of precipitation heat treating produce localized grain boundary precipitates adjacent to the depleted areas, producing susceptibility to intergranular corrosion. Additional heating, however, induces extensive general precipitation within the grains, lowering the corrosion potential differences between the grains and the boundary areas, thus removing the cause of the selective corrosion.

The most common test for susceptibility to intergranular corrosion is carried out as follows:

- Use a specimen that has at least 19 cm^2 (3 $in.^2$) of surface area
- Remove any cladding by filing or etching
- Clean the specimen by immersing it for 1 min in a solution containing 5% concentrated nitric acid and 0.5% hydrofluoric acid at a temperature of 95 °C (200 °F); rinse in distilled water. Immerse for 1 min in concentrated nitric acid at room temperature; rinse in distilled water
- Immerse the specimen for 6 h in a freshly prepared solution containing 57 g of sodium chloride and 10 mL of 30% hydrogen peroxide per liter of water at a temperature of 30 ± 5 °C (86 ± 9 °F). More than one specimen may be corroded in the same container provided that at least 4.6 mL of solution is used for each square centimeter (30 mL/$in.^2$) of specimen surface and that the specimens are electrically insulated from each other
- After the immersion period, wash the specimen with a soft-bristle brush to remove any loose corrosion product. Cut a cross-sectional specimen at least 19 mm ($\frac{3}{4}$ in.) long through the most severely corroded area; mount and metallographically polish this specimen
- Examine the cross-sectional specimen microscopically at magnifications of 100× and 500× both before and after etching with Keller's reagent
- Describe the results of the microscopic examination in terms of the five degrees of severity of

intergranular attack illustrated in Fig. 38

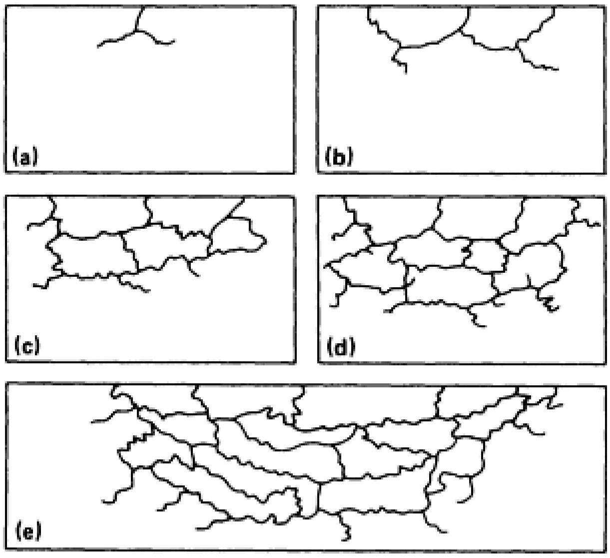

Fig. 38 Five degrees of severity of intergranular attack. Severity of intergranular attack (schematic), as observed microscopically in transverse sections after test for susceptibility to intergranular corrosion. Top of each area shown in surface exposed to corrosive solution

Electrical Conductivity. For control of the corrosion and stress-corrosion characteristics of certain tempers, notably the T73 and T76 types, the materials must meet combination criteria of yield strength plus electrical conductivity. Although these criteria are based on indirect measurements of properties, their validity for ensuring the intended corrosion and stress-corrosion resistance has been firmly established by extensive correlation and testing.

Low tensile strengths may be accompanied by high levels of electrical conductivity, so electrical conductivity is sometimes used as a quality-assurance diagnostic tool. However, because the correlation between strength and electrical conductivity is strongly a function of chemical composition and fabricating practice, use of electrical conductivity is not recommended except for rough screening. This screening must be followed by hardness testing, and then by tensile testing if the hardness tests indicate that the heat treatment was suspect.

Fracture Toughness Indices. Fracture toughness is rarely, if ever, a design consideration in the 1000, 3000, 4000, 5000, and 6000 series alloys. The fracture toughness of these alloys is sufficiently high that thicknesses beyond those commonly produced would be required to obtain a valid test.

Fracture toughness is a meaningful design-related parameter for some conventional high-strength alloys and all the controlled-toughness, high-strength alloys. Conventional aerospace alloys for which fracture toughness minimums may be useful in design include 2014, 2024, 2219, 7075, and 7079. These alloys have toughness levels that are inferior to those of their controlled-toughness counterparts. Consequently, these products are not used in fracture-critical applications, although fracture toughness can be a meaningful design parameter. Fracture toughness is not guaranteed in conventional high-strength alloys.

Fracture toughness quality control and material procurement minimums are appropriate for controlled-toughness, high-strength alloys. The alloys and tempers currently identified as controlled-toughness, high-strength products include:

Alloy	**Condition**	Product form

2048	T8	**Sheet and plate**
2124	T3, T8	**Sheet and plate**
2419	T8	**Sheet, plate, extrusions, and forgings**
7049	T7	**Plate, forgings, and extrusions**
7050	T7	**Sheet, plate, forgings, and extrusions**
7150	T6	**Sheet and plate**
7175	T6, T7	**Sheet, plate, forgings, and extrusions**
7475	**T6, T7**	**Sheet and plate**

The fracture toughness of these alloys and tempers range in measured K_{Ic} values from about 20 MPa$\sqrt{m}$ (18 ksi$\sqrt{in}$) upward. Controlled-toughness alloys are often derivatives of conventional alloys. For example, 7475 alloy is a derivative of 7075 with maximum compositional limits on some elements that were found to decrease toughness.

In products of the newer controlled-toughness high-strength alloys 2090, 2091, 2124, 2224, 2324, 7050, 7149, 7150, 7175, 7475, and 8090, which provide guaranteed levels of fracture toughness, minimum values of the applicable indices, K_{Ic} or K_c, are established by accumulation of statistical data from production lots as a basis for guaranteed minimum values. If the minimum specified fracture toughness value is not attained, the material is not acceptable. Some specifications allow use of less-expensive screening tests (such as the notch tensile or chevron-notched short bar) as a basis for release of high-toughness alloy products. In these instances, correlations between K_{Ic} and the screening test result is used to establish the appropriate notch-yield ratio as a lot-release criterion.

Temper Designations for Heat-Treatable Aluminum Alloys

The temper designations used in the United States for heat-treatable aluminum alloys are part of the system that has been adopted as an American National Standard (ANSI H35.1). Used for all wrought and cast product forms except ingot, the system is based on the sequences of mechanical or thermal treatments, or both, used to produce the various tempers. The temper designation follows the alloy designation and is separated from it by a hyphen. Basic temper designations consist of individual capital letters. Major subdivisions of basic tempers, where required, are indicated by one or more digits following the letter. These digits designate specific sequences of treatments that produce specific combinations of characteristics in the product. Variations in treatment conditions within major subdivisions are identified by additional digits. The conditions during heat treatment (such as time, temperature, and quenching rate) used to produce a given temper in one alloy may differ from those employed to produce the same temper in another alloy.

Designations for the common heat-treated tempers, and descriptions of the sequences of operations used to produce those tempers, are given in the following paragraphs. (For the entire aluminum alloy temper designation system, including designations for non-heat-treatable alloys, see *Properties and Selection: Nonferrous Alloys and Special-Purpose Materials,*Volume 2, *ASM Handbook.*

Basic temper designations for heat-treated conditions include the codes O, W, and T. Other basic temper designations are F (as fabricated) and H (strain hardened).

O, annealed. Applies to wrought products that are annealed to obtain lowest strength temper and to cast products that are annealed to improve ductility and dimensional stability. The O may be followed by a digit other than zero.

W, solution heat treated. An unstable temper applicable to any alloy that naturally ages (spontaneously ages at room temperature) after solution heat treatment. This designation is specific only when the period of natural aging is indicated--for example, W $\frac{1}{2}$h. (See also the discussion of the T*x*51, T*x*52, and T*x*54 tempers, in the section below on subdivision of the T temper.)

T, heat treated to produce stable tempers other than O. Applies to products that are thermally treated, with or without supplementary strain hardening, to produce stable tempers. The T is always followed by one or more digits, as discussed below.

Major Subdivisions of T Temper. In T-type designations, the T is followed by a number from 1 to 10; each number denotes a specific sequence of basic treatments, as described below.

T1, cooled from an elevated-temperature shaping process and naturally aged to a substantially stable condition. Applies to products that are not cold worked after an elevated-temperature shaping process such as casting or extrusion, and for which mechanical properties have been stabilized by room-temperature aging. If the products are flattened or straightened after cooling from the shaping process, the effects of the cold work imparted by flattening or straightening are not recognized in specified property limits.

T2, cooled from an elevated-temperature shaping process, cold worked, and naturally aged to a substantially stable condition. Applies to products that are cold worked specifically to improve strength after cooling from a hot-working process such as rolling or extrusion, and for which mechanical properties have been stabilized by room-temperature aging. The effects of cold work, including any cold work imparted by flattening or straightening, are recognized in specified property limits.

T3, solution heat treated, cold worked, and naturally aged to a substantially stable condition. Applies to products that are cold worked specifically to improve strength after solution heat treatment, and for which mechanical properties have been stabilized by room-temperature aging. The effects of cold work, including any cold work imparted by flattening or straightening, are recognized in specified property limits.

T4, solution heat treated and naturally aged to a substantially stable condition. Applies to products that are not cold worked after solution heat treatment, and for which mechanical properties have been stabilized by room-temperature aging. If the products are flattened or straightened, the effects of the cold work imparted by flattening or straightening are not recognized in specified property limits.

T5, cooled from an elevated-temperature shaping process and artificially aged. Applies to products that are not cold worked after an elevated-temperature shaping process such as casting or extrusion, and for which mechanical properties or dimensional stability, or both, have been substantially improved by precipitation heat treatment. If the products are flattened or straightened after cooling from the shaping process, the effects of the cold work imparted by flattening or straightening are not recognized in specified property limits.

T6, solution heat treated and artificially aged. Applies to products that are not cold worked after solution heat treatment, and for which mechanical properties or dimensional stability, or both, have been substantially improved by precipitation heat treatment. If the products are flattened or straightened, the effects of the cold work imparted by flattening or straightening are not recognized in specified property limits.

T7, solution heat treated and stabilized. Applies to products that have been precipitation heat treated to the extent that they are overaged. Stabilization heat treatment carries the mechanical properties beyond the point of maximum strength to provide some special characteristic, such as enhanced resistance to stress-corrosion cracking or to exfoliation corrosion.

T8, solution heat treated, cold worked, and artificially aged. Applies to products that are cold worked specifically to improve strength after solution heat treatment, and for which mechanical properties or dimensional stability, or both, have been substantially improved by precipitation heat treatment. The effects of cold work, including any cold work imparted by flattening or straightening, are recognized in specified property limits.

T9, solution heat treated, artificially aged, and cold worked. Applies to products that are cold worked specifically to improve strength after they have been precipitation heat treated.

T10, cooled from an elevated-temperature shaping process, cold worked, and artificially aged. Applies to products that are cold worked specifically to improve strength after cooling from a hot-working process such as rolling or extrusion, and for which mechanical properties or dimensional stability, or both, have been substantially improved by precipitation heat treatment. The effects of cold work, including any cold work imparted by flattening or straightening, are recognized in specified property limits.

Other Subdivisions of T Temper Codes for Stress-Relieved Products. When it is desirable to identify a variation of one of the ten major T tempers described above, additional digits, the first (*x*) of which cannot be zero, may be added to the designation.

The following specific sets of additional digits have been assigned to stress-relieved wrought products.

Tx51, stress relieved by stretching. Applies to the following products when stretched to the indicated amounts after solution heat treatment or after cooling from an elevated-temperature shaping process:

Product form	Permanent set, %
Plate	**$1\frac{1}{2}$-3**
Rod, bar, shapes, extruded tube	**1-3**
Drawn tube	**$\frac{1}{2}$-3**

T*x*51 applies directly to plate and to rolled or cold finished rod and bar. These products receive no further straightening after stretching. T*x*51 also applies to extruded rod, bar, shapes, and tubing, and to drawn tubing, when designated as follows:

- T*x*510. Products that receive no further straightening after stretching
- T*x*511. Products that may receive minor straightening after stretching to comply with standard tolerances
- T*x*52. Stress relieved by compressing. Applies to products that are stress relieved by compressing after solution heat treatment, or after cooling from a hot-working process to produce a permanent set of 1 to 5%
- T*x*54. Stress relieved by combining stretching and compressing. Applies to die forgings that are stress relieved by restriking cold in the finish die. (These same digits--and 51, 52, and 54--may be added to the designation W to indicate unstable solution heat-treated and stress-relieved tempers)

Temper designations T42 and T62 have been assigned to wrought products heat treated from the O or the F temper to demonstrate response from the heat treatment described below. Temper designations T42 and T62 also may be applied to wrought products heat treated from any temper by the user when such heat treatment results in the mechanical properties applicable to these tempers.

- *T42.* Solution heat treated from the O or the F temper to demonstrate response to heat treatment and naturally aged to a substantially stable condition
- *T62.* Solution heat treated from the O or the F temper to demonstrate response to heat treatment and

artificially aged

Subdivision of the O Temper. In temper designations for annealed products, a digit following the O indicates special characteristics. For example, O1 denotes that a product has been heat treated according to a time/temperature schedule approximately the same as that used for solution heat treatment, and then air cooled to room temperature, to accentuate ultrasonic response and provide dimensional stability; this designation applies to products that are to be machined prior to solution heat treatment by the user.

Heat Treating of Copper Alloys

Revised by Arthur Cohen, Copper Development Association Inc.

Introduction

HEAT-TREATING PROCESSES that are applied to copper and copper alloys include homogenizing, annealing, stress relieving, solution treating, precipitation (age) hardening, and quench hardening and tempering.

Homogenizing

Homogenizing is a process in which prolonged high-temperature soaking is used to reduce chemical or metallurgical segregation commonly known as coring, which occurs as a natural result of solidification in some alloys. Homogenizing is applied to copper alloys to improve the hot and cold ductility of cast billets for mill processing, and occasionally is applied to castings to meet specified hardness, ductility, or toughness requirements.

Homogenization is required most frequently for alloys having wide freezing ranges, such as tin (phosphor) bronzes, copper nickels, and silicon bronzes. Although coring occurs to some extent in α brasses, α-aluminum bronzes, and copper-beryllium alloys, these alloys survive primary mill processing and become homogenized during normal process working and annealing. Rarely is it necessary to apply homogenization to finished or semifinished mill products.

A characteristic of high cooling rates is the uneven distribution of the alloy elements in the interior of the dendritic microstructure. These differences increase with higher cooling rates and greater differences in composition between melt and solid phase at the onset of crystallization. This difference may be equalized in some alloys by long-time homogenization as a result of diffusion processes taking place in the solid phase.

The time and temperature required for the homogenization process vary with the alloy, the cast grain size, and the desired degree of homogenization. Typical soak times vary from 3 to over 10 h. Temperatures normally are above the upper annealing range, to within 50 °C (90 °F) of the solidus temperature.

Homogenization changes the mechanical properties: ultimate tensile strength, hardness, and yield (proof) strength all slowly decrease, whereas elongation at fracture and necking increase by as much as twice the initial value. Figure 1 shows a typical example of these changes taking place at a homogenizing time of 4 h for alloy C52100, a wrought phosphor bronze alloy containing nominally 92% Cu, 8% Sn, a small amount of phosphorus, and trace amounts of several other elements.

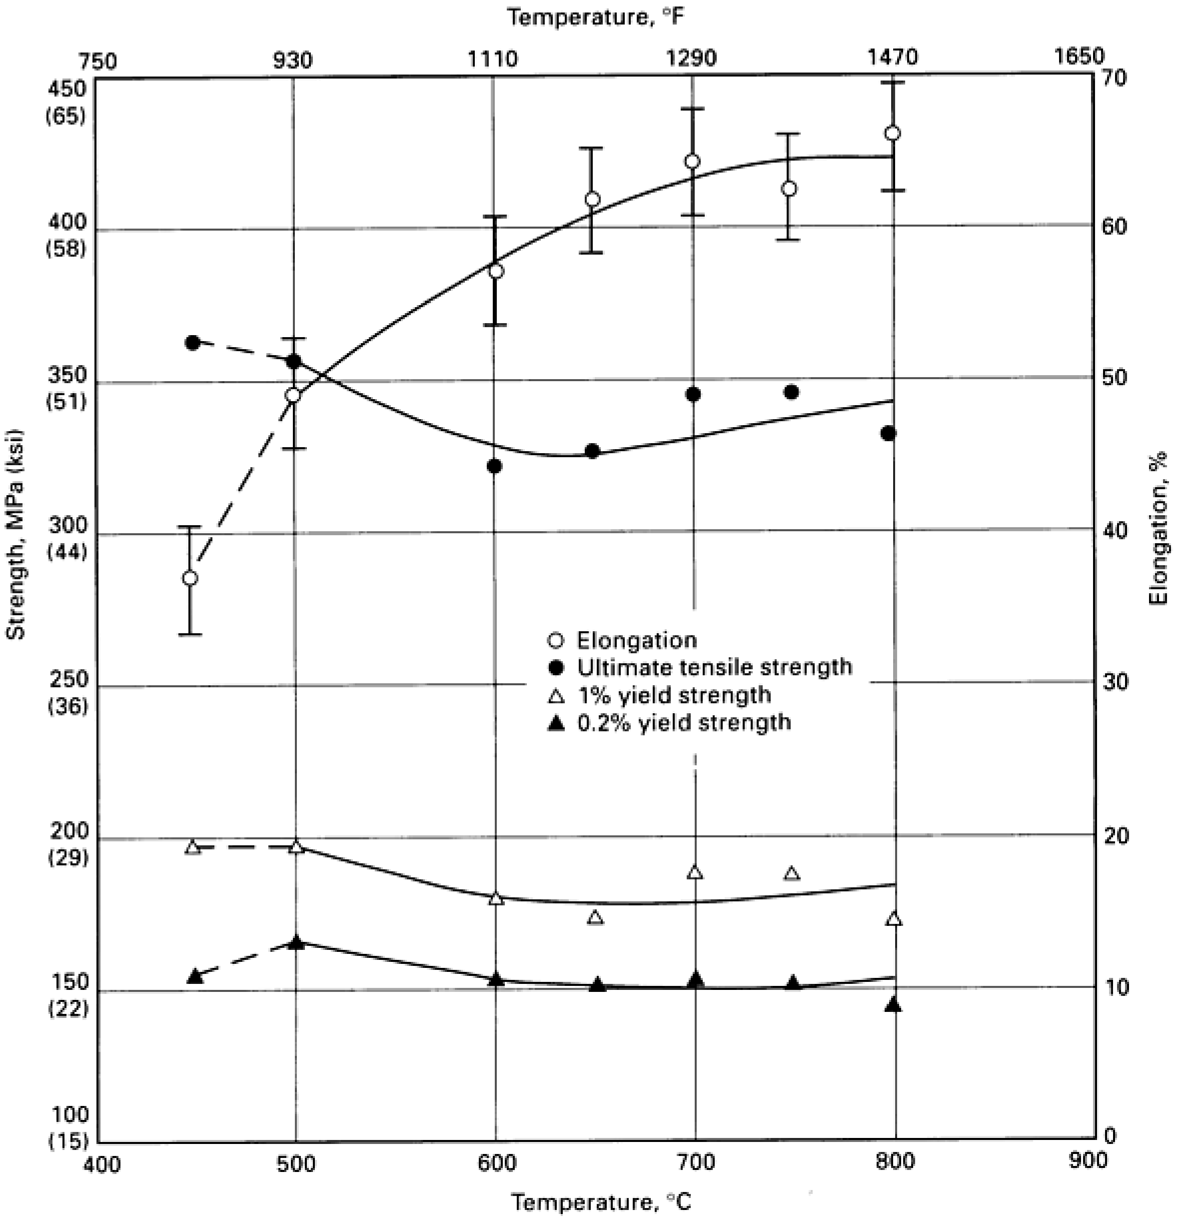

Fig. 1 Effect of annealing temperature on the mechanical properties of an alloy C52100 slab. Annealing time, 4 h

The normal precautions that apply to annealing should be used for the homogenization of any particular alloy. The furnace atmosphere should be selected for the control of both surface and internal oxidation. Where there is appreciable danger of liquefying segregated phases, the materials, particularly castings, should be well supported and heated slowly through the final 100 °C (180 °F).

Typical applications of homogenization are:

- Alloy C71900 (copper-nickel-chromium) billets: 1040 to 1065 °C (1900 to 1950 °F) for 4 to 9 h, to prevent cracks, seams, and excessive wood fiber structure in extrusions
- Alloy C52100 and C52400 (phosphor bronzes, 8 and 10% Sn): 775 °C (1425 °F) for 5 h, to reduce embrittlement in billets and slabs that are to be cold rolled
- Alloy C96400 (cast 70Cu-30Ni): 1000 °C (1830 °F) for 2 h under a protective atmosphere and then cooled to 400 °C (750 °F), followed by air cooling

For the precipitation-hardenable alloys, homogenization may involve a prolonged solution treatment.

Annealing

Annealing is a heat treatment intended to soften and to increase the ductility and/or toughness of metals and alloys. Annealing is applied to wrought products, during and after mill processing, and to castings. The process includes heating, holding, and cooling, and a proper process description should include heating rate, temperature, time at temperature, atmosphere, and cooling rate where each may affect results.

Wrought Products

The annealing of cold-worked metal is accomplished by heating to a temperature that produces recrystallization and, if desirable, by heating beyond the recrystallization temperature to initiate grain growth. Temperatures commonly used for annealing cold-worked coppers and copper alloys are given in Table 1.

Table 1 Annealing temperatures for widely used cold-worked copper and copper alloys

Alloy	**Common name**	Annealing temperature	
		°C	°F
Wrought coppers			
C10100-C10300	Oxygen-free copper	375-650	**700-1200**
C10400-C10700	Oxygen-free silver-bearing copper	475-750	**900-1400**
C10800	Oxygen-free low-phosphorus copper	375-650	**700-1200**
C11000	Electrolytic tough-pitch copper	250-650	**500-1200**
C11100	Electrolytic tough-pitch, anneal-resistant copper	475-750	**900-1400**
C11300, C11400, C11500, C11600	Silver-bearing tough pitch copper	400-475	**750-900**
C12000	Phosphorus-deoxidized copper, low residual phosphorus	375-650	**700-1200**
C12200	Phosphorus-deoxidized copper, high residual phosphorus	375-650	**700-1200**
C12500, C12700, C13000	Fire-refined, tough-pitch copper with silver	400-650	**750-1200**
C14500	Phosphorus-deoxidized, tellurium-bearing copper	425-650	**800-1200**
C14700	Sulfur copper	425-650	**800-1200**

(a) Solution-treating temperature; see Table 6 for temperatures for specific alloys.

(b) Cool rapidly (cooling method important in determining result of annealing).

(c) Air cool (cooling method important in determining result of annealing).

Annealing is primarily a function of metal temperature and time at temperature. Except for multiphase alloys, including certain precipitation-hardening alloys, and alloys susceptible to fire cracking, rates of heating and cooling are relatively unimportant. On the other hand, the source and application of heat, furnace design, furnace atmosphere, and shape of the workpiece are important because they affect finish, cost of annealing, and uniformity of results obtained.

The multiplicity of influential variables (such as temperature, time, and furnace load) make it difficult to tabulate a definite annealing schedule that will result in completely recrystallized metal of a specific grain size. The effects of annealing temperature on the tensile strength, elongation, and grain size of hard-drawn (63%) C27000 (yellow brass) wire annealed for 1 h and the effect of annealing time on the grain size of C27000 strip are shown in Fig. 2.

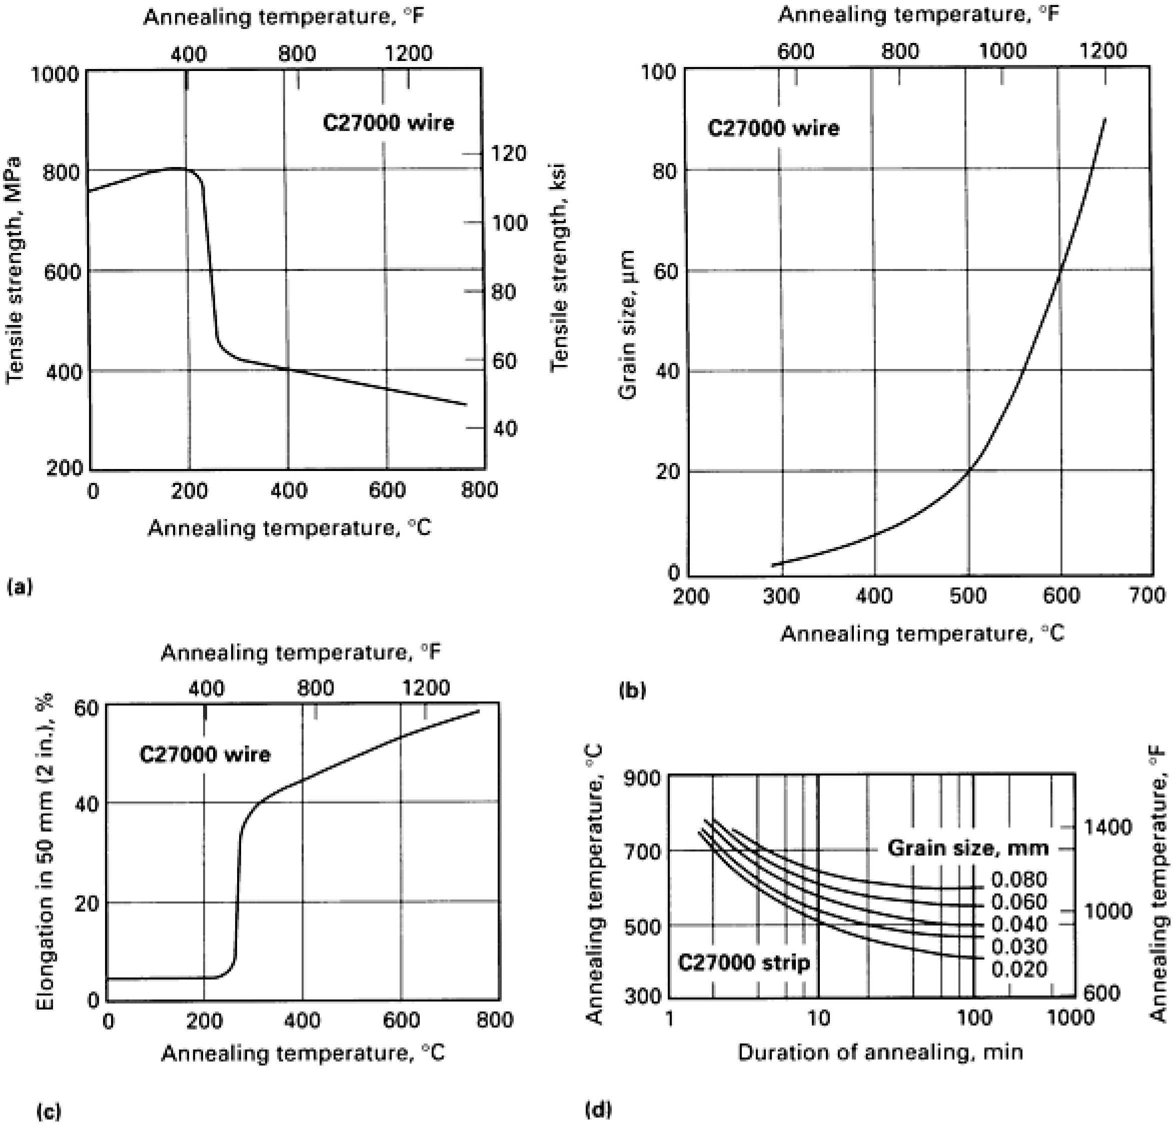

Fig. 2 Effects of annealing temperature and time on characteristics of C27000 wire and strip. Effects of annealing temperature (annealing time, 1 h) on (a) tensile strength, (b) grain size, and (c) elongation of C27000 wire hard drawn 63%. (d) Effect of annealing time on grain size of C27000 strip 1.3 mm (0.050 in.) thick

The annealing response of alloy C26000 (cartridge brass) strip after a reduction of 40.6% by cold rolling is shown in Fig. 3. Time at temperature was 1 h. The actual increases in hardness and tensile properties shown at temperatures below the recrystallization range are typical of alloys such as brasses, nickel silvers, phosphor bronzes, and α-aluminum bronzes. Depending on the individual alloy, these increases are attributable to phenomena of the strain-aging and/or lattice-ordering type.

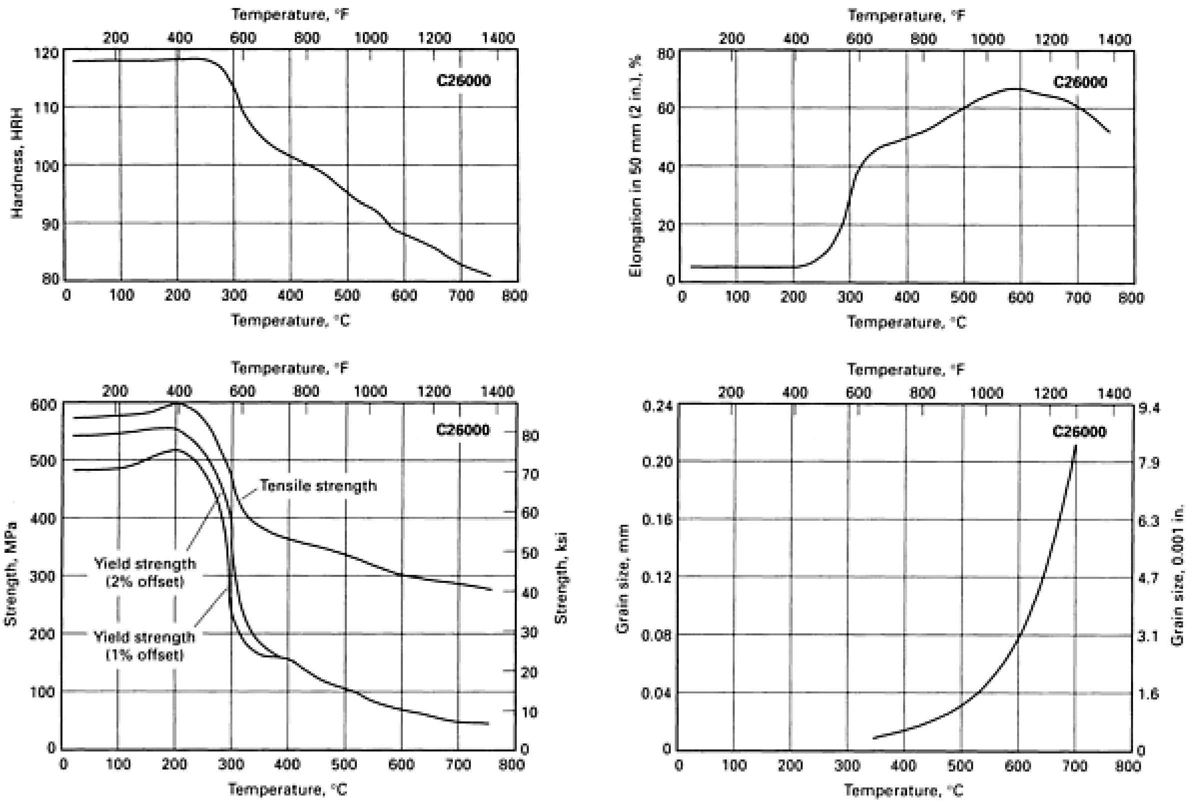

Fig. 3 Annealing data for alloy C26000. Finish rolling reduction 40.6%

Methods of rapid recrystallization have gained importance in heat treatment technology. Softening time can be significantly reduced, compared to conventional annealing processes, by increased heating rates using higher temperatures. However, these heat treat parameters may affect the mechanical properties of the materials.

An increased amount of cold work prior to annealing lowers the recrystallization temperature. The lower the degree of prior deformation, the larger the grain size after annealing. For a fixed temperature and duration of annealing, the larger the original grain size before working, the larger the grain size after recrystallization.

In commercial mill practice, copper alloys are usually annealed at successively lower temperatures as the material approaches the final anneal, with intermediate cold reductions of at least 35% and as high as 50 to 60% in single or multiple passes wherever practicable. The higher initial temperatures accelerate homogenization, and the resulting large grains permit a more economical reduction during the early working operation.

During subsequent anneals, the grain size should be decreased gradually to approximate the final grain size required. This point is usually reached one or two anneals before the final anneal. With such a sequence and with sufficiently severe intermediate reductions, it is possible to produce a uniform final grain size within a lot and from lot to lot.

The grain size and mechanical properties required for further cold working vary considerably with the alloy and with the amount and kind of further cold work to be done. The goal of annealing for cold working is to obtain the optimum combination of ductility and strength. However, when press-drawn parts are to be finished by polishing and buffing, the grain size should be as fine as practicable to keep the surface texture smooth and thus to avoid the need for excessive buffing and the attendant costs. The anneal must be governed by definite specifications and coordinated with cold-working operations to yield the desired finished properties.

Because the annealing of closed strip in tightly wound coils of large weight causes uneven heating in the individual layers corresponding to the direction of heat flow, uneven deep-drawing properties and variations in size may result.

These difficulties led to the development of the continuous-strip furnace (Fig. 4a) through which the material to be annealed passes in a single strip. The annealing temperature for the entire length is dependent only on the furnace temperature and the speed of travel of the strip through the furnace.

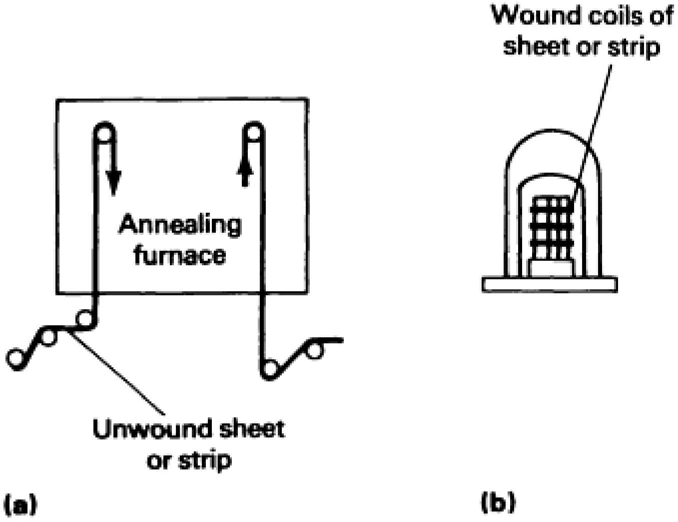

Fig. 4 Types of annealing. (a) Continuous. (b) Batch

The very large surface area with respect to weight permits extremely rapid heating of the metal strip in comparison to previous annealing methods. The annealing time can be measured accurately in seconds by controlling the speed of travel.

Annealing to Specific Properties

Although specific properties are most frequently produced by the controlled cold working of annealed material, there are occasions in which annealing to temper is necessary or advantageous. In the hot rolling of copper alloy plate--particularly plate of large pattern--the finishing temperature may not be consistent or controllable, and varying degrees of work hardening may occur. Also, small quantities and/or odd sizes of required drawn or roll-tempered materials may not be readily available, while appropriate stocks of harder material may be. Thin-gage strip (0.25 mm, or 0.010 in., thick) for radiator fabrication produced by annealing to temper is more closely controlled and more suitable for fabrication than strip in cold-worked tempers. In each case, an anneal is used to alter hardness and tensile properties to levels between those of the hard and fully annealed tempers, with reasonably predictable results. For most copper alloys, the rapid drops in tensile properties and hardness that occur with an increase in temperature in the annealing range necessitate the very close control of the annealing process to produce the desired results. Temperatures used are those in the lower annealing range, with special precautions taken to avoid any overheating. The resultant microstructures may indicate incomplete recrystallization for the harder tempers and grain sizes generally up to 0.025 mm (0.001 in.) for softer tempers. Tensile strengths and hardness levels similar to those of $\frac{1}{8}$, $\frac{1}{4}$, and $\frac{1}{2}$ hard cold-worked tempers can be produced by annealing hard-worked brasses, nickel silvers, and phosphor bronzes. While the yield strength for a given final hardness tends to be lower for alloys annealed to temper than for those cold worked to temper, the fatigue resistance of some phosphor bronze spring materials in annealed $\frac{1}{2}$ hard tempers appears to be superior to that of cold-worked material. Table 2 gives typical properties of annealed-to-temper mill materials. The successful use of annealing to provide specific tempers in mill products requires well-regulated working and annealing schedules designed to produce homogeneous material with controlled grain size, such that the final anneal can produce a uniform result throughout a given lot.

Table 2 Typical properties of copper alloys annealed to temper

Alloy	**Common name**	**Annealed temper**	**Tensile strength**	Approximate hardness, HR30T

		Standard designation	Former designation	MPa	ksi	hardness, HR30T
C26000	Cartridge brass	O81	$\frac{1}{4}$ hard	340-405	49-59	**43-51**
		O82	$\frac{1}{2}$ hard	395-460	57-67	**56-66**
C51100, C53200, C53400, C54400	Phosphor bronze	O82	$\frac{1}{2}$ hard	380-485	55-70	**57-73**
C75200	Nickel silver	O81	$\frac{1}{4}$ hard	400-495	58-72	**49-67**
		O82	$\frac{1}{2}$ **hard**	**455-550**	**66-80**	**62-72**

General Precautions

For best results in annealing copper and copper alloys, the precautions discussed below should be observed.

Sampling and Testing. Test specimens must represent the extreme conditions of the furnace load. For copper alloys that do not contain grain-growth inhibitors, the best and most accurate test for the extent of annealing is the size of the average grain. Grain size is usually the basis for acceptance or rejection of the material. This determination requires special equipment not always available in the plants of consumers or fabricators. For convenience in testing, Rockwell-type hardness testers are used to approximate the grain size; ASTM specifications correlate Rockwell hardness with grain size values for many copper alloys.

Effect of Pretreatment. Because the amount of cold working and the anneal prior to cold working greatly affect the results of annealing after cold working, any schedule that is set up must take this pretreatment into account. Once a schedule has been established, both the anneal and the pretreatment must be adhered to for consistent results.

Effect of Time. In most furnaces, there is an appreciable difference between the temperature of the metal and that of the furnace. Consequently, time in the furnace greatly affects the final temperature of the metal. For a fixed anneal and furnace temperature, time must vary with the type of work load.

Oxidation should be held to a minimum to reduce the loss of metal and the cost of pickling and to improve surface finish. In some instances, specially prepared atmospheres are used to produce a bright annealed material. Usually the control of furnace atmosphere also results in better furnace economy.

Effect of Lubricants. Lubricants on metal to be annealed may cause staining that is difficult to remove. Regardless of the type of furnace or the article to be annealed, it is advisable to eliminate as much of the lubricant as possible before the metal is heated by degreasing or washing.

Hydrogen Embrittlement. When copper that contains oxygen (tough-pitch copper) is to be annealed, the hydrogen in the furnace atmosphere must be kept to a minimum. This reduces the embrittlement caused by the combination of the hydrogen in the atmosphere with the oxygen in the copper, forming water vapor under pressure and resulting in minute porosity in the metal. For temperatures lower than about 480 °C (900 °F), the hydrogen content of the atmosphere preferably should not exceed 1%, and as the temperature is increased, the hydrogen content should approach 0.

Impurities. Occasionally, it is difficult to obtain proper grain growth by annealing under standard conditions that previously have resulted in the desired grain size. This difficulty may sometimes be traced to impurities in the alloy.

Loading. It usually is inadvisable to anneal a variety of different sizes or kinds of material in the same charge because of the different rates of heating and the resulting final metal temperatures.

Fire cracking occurs when some alloys that contain residual stresses are heated too rapidly. Leaded alloys are particularly susceptible to fire cracking. The remedy is to heat slowly until the stresses are relieved. Special types of cold deformation, such as springing (flexing or reeling through a straightener), aid considerably in preventing fire cracking by inducing countervailing mechanical stresses.

Thermal shock or fatigue takes place when rapid and extreme changes in temperatures occur. Stresses that result in thermal shock are influenced by thermal expansion, thermal conductivity, strength, toughness, the rate of temperature change, and the condition of the material. Brasses containing lead, lead and tin, or lead and certain impurities including bismuth or tellurium may be hot short. If they are repeatedly subjected to extreme temperature changes, they may be subject to thermal shock, especially if highly stressed in tension on the surface.

Cooling. Alpha brasses containing less than 70% copper may contain some β phase that is formed during casting or during heat treatment above 600 °C (1110 °F), especially if the metal section is massive. Quenching rapidly will entrap the β phase in the brass. Slow cooling will permit the time and temperature to convert the β to the α phase.

Sulfur Stains. Excessive sulfur in the fuel or lubricant will cause discoloration of the metal; red stains appear on yellow brass, and black or reddish-brown stains on copper-rich alloys.

Castings

Annealing is applied to castings of some duplex alloys, such as manganese bronzes and aluminum bronzes, in order to correct the effects of mold cooling. The extremely slow cooling of sand and plaster castings, or the rapid cooling of permanent mold or die castings, can produce microstructures resulting in hard hardness and/or low ductility and occasionally inferior corrosion resistance. Typical annealing treatments for castings are in the range of 580 to 700 °C (1075 to 1300 °F) for 1 h at temperature. For aluminum bronzes, rapid cooling by water quenching or high-velocity air is advisable.

Stress Relieving

Stress relieving is a process intended to relieve internal stress in materials or parts without appreciably affecting their properties. Stress-relieving heat treatments are applied to wrought or cast copper and copper alloys as one means of accomplishing this objective.

During the processing or fabrication of copper or copper alloys by cold working, strength and hardness increase as a result of plastic strain. Because plastic strain is accompanied by elastic strain, residual stresses remain in the resultant product. If allowed to remain in sufficient magnitude, residual surface tensile stresses can result in stress-corrosion cracking of material in storage or service, unpredictable distortion of material during cutting or machining, and hot cracking of materials during processing, brazing, or welding. In brasses that contain more than 15% Zn, stress-corrosion cracking, or "season cracking," can occur if sufficient amounts of residual tensile stress and trace amounts of atmospheric ammonia are present. Other copper alloys, such as cold-worked aluminum bronzes and silicon bronzes, may also suffer stress-corrosion cracking under more severe environments.

Although mill practice for stress relief frequently involves mechanical means such as flexing, cross-roll straightening, or shot peening, stress-relief heat treatments are employed for some tubular products and odd shapes. Thermal stress relief is also used for formed parts and fabrications made by material users. It is important to recognize that thermal stress relief reduces residual stress by eliminating part of the residual elastic strain, whereas mechanical stress relief merely redistributes residual stress into a less detrimental pattern.

Stress-relief heat treatments are carried out at temperatures below those normally used for annealing. Typical process stress-relieving temperatures for selected coppers and copper alloys are given in Table 3 (wrought products) and Table 4 (cast products). Temperatures for the treatment of cold-formed or welded structures are generally 50 to 110 °C (90 to 200 °F) higher than the temperatures in Table 3. In the case of the weld repair of ship propellers, for example, care must be

exercised to prevent the buildup of excessive residual stresses in the weld zone because such stresses may lead to accelerated corrosion attack. Current propeller repair specifications require post-weld treatment for the aluminum and manganese bronze weldments. Heat treatment of the aluminum bronze at 565 or 650 °C (1050 to 1200 °F) imparts the best overall corrosion resistance to the heat-affected zone. Manganese bronze weldments are not susceptible to stress-corrosion cracking when subjected to yield stress loading in flowing seawater. Heat treatment in the range of 200 to 540 °C (400 to 1000 °F) does not significantly change the tensile, corrosion-fatigue, or general corrosion properties of manganese bronze.

Table 3 Typical stress-relieving temperatures for wrought coppers and copper alloys

Table 4 Typical stress-relieving temperatures for cast copper alloys

Copper alloy number	Temperature	
	°C	°F
C81300-C82200	260	**500**
C82400-C82800	200	**390**

C83300-C84800	260	**500**
C95200-C95800	315	**600**
C96600-C97800	260	**500**
C99300	**510**	**950**

Note: Time is 1 h per 25 mm (1 in.) of section thickness except for copper alloy C99300, for which it is 4 h per 25 mm (1 in.).

From a practical standpoint, higher-temperature/shorter-time treatments are preferable. However, to guarantee the preservation of mechanical properties, lower temperatures and longer times are sometimes necessary. The optimum cycle produces adequate stress relief without adversely affecting properties. As shown in Fig. 2, some alloys may undergo slight increases in property values during stress-relief heat treatment.

To detect the presence of significant residual stress and to evaluate the effectiveness of stress-relieving treatments, samples of material may be tested with mercurous nitrate solutions, as described in ASTM B 154. This test method is an accelerated test for detecting the presence of residual (internal) stresses, which might result in failure of individual parts in storage or in service due to stress-corrosion cracking. It is not intended for testing assemblies of fabricated parts from mill products. Because of the hazards of mercurous salts, tests in high concentrations of moist ammonia have also been used. Warping of rod or tube during longitudinal saw slitting has also been used as a crude field test for residual stress.

Hardening

Copper alloys that are hardened by heat treatment are of two general types: those that are softened by high-temperature quenching and hardened by lower-temperature precipitation heat treatments, and those that are hardened by quenching from high temperatures through martensitic-type reactions. Alloys that harden during low-to-intermediate-temperature treatments following solution quenching include precipitation-hardening, spinodal-hardening, and order-hardening types. Quench-hardening alloys comprise aluminum bronzes, nickel-aluminum bronzes, and a few special copper-zinc alloys. Usually quench-hardened alloys are tempered to improve toughness and ductility and reduce hardness in a manner similar to that used for alloy steels.

Low-Temperature-Hardening Alloys

For purposes of comparison, Table 5 lists examples of the various types of low-temperature-hardening alloys, as well as typical heat treatments and attainable property levels for these alloys. Additional details are given in the three subsections below.

Table 5 Typical heat treatments and resulting properties for several low-temperature-hardening alloys

Alloy	**Solution-treating temperature**[(a)]		**Aging treatment**			**Hardness**	Electrical conductivity, % IACS[(b)]

(a) Solution treating is followed by water quenching.

(b) International Annealed Copper Standard.

(c) Alloy C18000 (81540) must be double aged, typically 3 h at 540 °C (1000 °F) followed by 3 h at 425 °C (800 °F) (U.S. Patent 4,191,601) in order to develop the higher levels of electrical conductivity and hardness.

Precipitation-Hardening Alloys. Most copper alloys of the precipitation-hardening type find use in electrical and heat conduction applications. Therefore the heat treatment must be designed to develop the necessary mechanical strength and electrical conductivity. The resulting hardness and strength depend on the effectiveness of the solution quench and the control of the precipitation (aging) treatment. It should be noted that the terms age hardening and aging are used in heat-treating practice as substitutes for the term precipitation hardening or a spinodal hardening. Copper alloys harden by elevated-temperature treatment rather than ambient-temperature (natural) aging, as in the case of some aluminum alloys. As dissolved atoms proceed through the coagulation, coherency, and precipitation cycle in the quenched alloy lattice, hardness increases, reaches a peak, and then decreases with time. Electrical conductivity increases continuously with time until some maximum is reached, normally in the fully precipitated condition. The optimum condition generally preferred results from a precipitation treatment of temperature and duration just beyond those that correspond to the hardness aging peak. Cold working prior to precipitation aging tends to improve heat-treated hardness. In the case of lower-strength wrought alloys such as C18200 (copper-chromium) and C15000 (copper-zirconium), some heat-treated hardness may be sacrified to attain increased conductivity, with final hardness and strength being enhanced by cold working. Two

precipitation treatments are necessary in order to develop maximum electrical conductivity and hardness in alloy C18000 (copper-nickel-silicon-chromium) because of two distinct precipitation mechanisms.

Certain guidelines can be used to diagnose problems encountered in producing desired properties in precipitation-hardening alloys:

Problem	Diagnosis
Low hardness	**Solution temperature too low; solution quench delayed or cooling rate too low; aging temperature too low and/or time too short (underaging) or temperature too high and/or time too long (overaging)**
Low hardness; low conductivity	**Inadequate solution treatment and/or underaging**
Low hardness; high conductivity	**Inadequate solution treatment and/or overaging**
High hardness; low conductivity	**Underaging; contaminated material**

When precipitation hardening is performed at the mill, further treatment following the fabrication of parts is not required. However, it may be desirable to stress relieve parts in order to remove stresses induced during fabrication, particularly for highly formed cantilever-type springs and intricate, machined shapes that require maximum resistance to relaxation at moderately elevated temperatures.

Spinodal-Hardening Alloys. Alloys that harden by spinodal decomposition are hardened by a treatment similar to that used for precipitation-hardening alloys. The soft, ductile spinodal structure is generated by a high-temperature solution treatment followed by quenching. The material can be cold worked or formed in this condition. A lower-temperature spinodal-decomposition treatment, commonly referred to as aging, is then used to increase the hardness and strength of the alloy. Spinodal-hardening alloys are basically copper-nickel alloys with chromium or tin additions. The hardening mechanism is related to a miscibility gap in the solid solution and does not result in precipitation. The spinodal-hardening mechanism does result in the chemical segregation of the α crystal matrix on a very fine (Ångström) scale and requires the use of the electron microscope to discern the metallographic effects. Because no crystallographic changes take place, spinodal-hardening alloys retain excellent dimensional stability during hardening.

Order-Hardening Alloys. Certain alloys, generally those that are nearly saturated with an alloying element dissolved in the α phase, undergo an ordering reaction when highly cold worked material is annealed at a relatively low temperature. Alloys C61500, C63800, C68800, and C69000 are examples of copper alloys that exhibit this behavior. Strengthening is attributed to the short-range ordering of the dissolved atoms within the copper matrix, an ordering which greatly impedes the motion of dislocations through the crystals.

The low-temperature order-annealing treatment also acts as a stress-relieving treatment, which raises yield strength by reducing stress concentrations in the lattice at the focuses of dislocation pileups. As a result, order-annealed alloys exhibit improved stress-relaxation characteristics.

Order annealing is done for relatively short times at relatively low temperatures, generally in the range from 150 to 400 °C (300 to 750 °F). Because of the low temperature, no special protective atmosphere is required. Order hardening is frequently done after the final fabrication step to take full advantage of the stress-relieving aspect of the treatment, especially where resistance to stress relaxation is desired.

Quench Hardening and Tempering

Quench hardening and tempering (also referred to as quench and temper hardening) is used primarily for aluminum bronze and nickel-aluminum bronze alloys, and occasionally for some cast manganese bronze alloys with zinc equivalents of 37 to 41%. Aluminum bronzes with 9 to 11.5% Al, as well as nickel-aluminum bronzes with 8.5 to 11.5% Al, respond in a practical way to quench hardening by a martensitic-type reaction. Generally alloys higher in aluminum content are too susceptible to quench cracking, whereas those with lower aluminum contents do not contain enough high-temperature β phase to respond to quench treatments.

Heat-Treating Equipment

Although basic furnace design is similar for all copper alloys, consideration must be given to the annealing temperature range and method of cooling. Solid-solution alloys that do not precipitation harden are usually annealed at temperatures below 760 °C (1400 °F) and may be cooled at any convenient rate. Precipitation- or spinodal-hardenable alloys are solution treated at temperatures up to 1040 °C (1900 °F) and require rapid quenching to ambient temperatures.

Batch-type atmosphere furnaces (Fig. 4b) may be heated electrically or by oil or gas. When nonexplosive atmospheres are used, electrically heated furnaces permit the atmosphere to be introduced directly into the work chamber.

Furnaces that are heated by gas or oil and that employ protective atmospheres sometimes have a muffle to contain the atmosphere and protect the work from the direct fire of the burners.

A properly constructed and safely operated muffle that prevents the infiltration of air by maintaining positive pressure is always required when explosive atmospheres, such as hydrogen, are used.

When protective atmospheres are used during annealing, the work must be cooled in the atmosphere almost to room temperature to prevent surface scale or discoloration. Metal temperatures above 65 °C (150 °F) in air may result in light tarnishing. If some degree of surface oxidation and discoloration can be tolerated, direct-natural-gas-fired furnaces may be used. The products of combustion from the gas-air burners are controlled to yield reducing combustion products similar in composition to manufactured protective atmospheres. Parts annealed in reducing atmospheres developed by the control of the furnace air-to-gas ratio require cleaning to restore luster.

Continuous atmosphere furnaces (Fig. 4(a) and 5) offer versatility for solution heat treating a wide variety of products. Usually, the furnace consists of a vestibule that provides a seal for the atmosphere and in some instances preheats the work, a heating chamber of sufficient length to ensure complete solution treating, and a cooling or quenching chamber that also serves as an atmosphere seal.

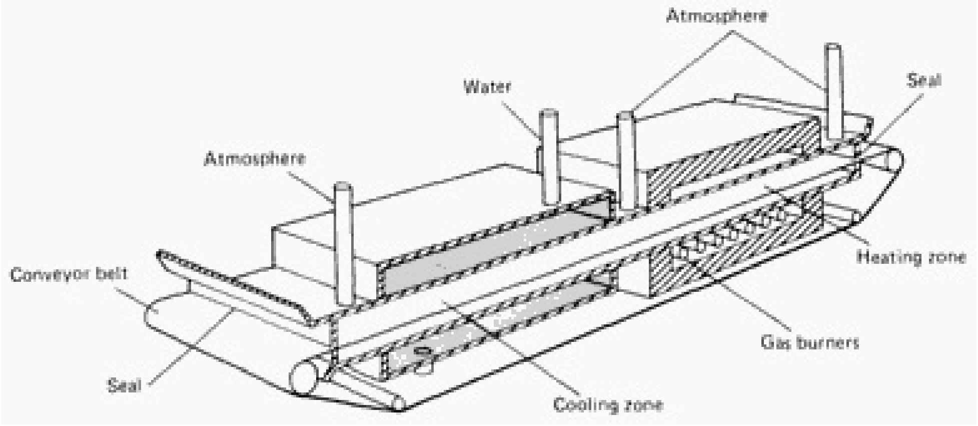

Fig. 5 Continuous conveyor furnace for heat treating copper alloys in a controlled atmosphere

Because the work is usually conveyed at a fixed rate through the furnace, moderate temperature gradients are less harmful than in batch furnaces. When long heating chambers are required, the furnace may be divided into more than one

temperature-controlled heating zone. It is practical to develop a high temperature in the entrance zone to facilitate the heating of the work to the desired temperature. The cooling chamber may be either a long tunnel through which cool, protective atmosphere is circulated or a water-quench zone supplied with a protective atmosphere.

Products such as stampings, machined shapes, castings, and small assemblies are conveyed through the furnace on an endless belt or conveyor chain. Long sections such as tubing, bar, and flat products, or heavy sections that permit stacking on trays, may be conveyed on a roller hearth. In rolling-mill operations, the product is uncoiled at the entrance of the furnace and pulled through the furnace by terminal equipment at the exit end; thus, there are no moving parts within the furnace. For wire products, either annealing is carried out in bell furnaces, with the wire reel wound, or in-line resistance annealing is performed upon exit of the product from the drawing machine prior to reel winding.

Salt Baths. Molten neutral salts may be used for the annealing, stress relieving, solution heat treating, or aging of copper alloys. The composition of the salt mixture depends on the temperature range required. For heating between 705 and 870 °C (1300 and 1600 °F), mixtures of sodium chloride and potassium chloride are commonly used. Various mixtures of barium chloride with sodium and potassium chlorides are used for a wider temperature range (595 to > 1095 °C, or 1100 to > 2000 °F). The latter mixtures are compatible with each other and are commonly used in multiple-furnace operations when it is advantageous to preheat the work in one mixture at a low temperature and then transfer the work to a high-temperature bath. The least common neutral salts are mixtures of calcium chloride, sodium chloride, and barium chloride. They have an operating temperature range of 540 to 870 °C (1000 to 1600 °F) but usually are operated between 540 and 650 °C (1100 and 1200 °F).

The sodium chloride-carbonate mixtures (not true neutral salts) are used between 595 and 925 °C (1100 and 1700 °F), primarily for annealing. For operating temperatures below 540 °C (1000 °F), the only practical mixtures are the nitrate-nitrite salts. Cyanide-base salts have limited application for heating copper alloys. Although copper is soluble in cyanide, these salts can be used, with caution, when a very bright finish is required.

None of the above salt mixtures can be used for the solution treating of standard beryllium-copper alloys because of intergranular attack, pitting, or discoloration.

Aging and stress-relieving operations require furnace equipment that can be controlled to within 3 °C (5 °F) throughout the work zone. Unless cleaning after heating is permissible, it may be necessary to use controlled-atmosphere or vacuum equipment.

Because of the necessity for close temperature control, forced-convection (recirculating-air) and salt bath furnaces are commonly used for aging and stress relieving. Forced-convection furnaces may be of the box, bell, or pit type. Each is equipped with a fan that recirculates the constant-temperature atmosphere over the work. When forced-convection furnaces are fired by gas or oil and protective atmosphere or vacuum is used, the work must be contained in a properly operating muffle chamber or retort to seal off all products of combustion and to prevent air infiltration. Temperature variations and heating and cooling times are compared in the example below.

Example 1: Comparison of Atmosphere Furnaces and Salt Bath Treatment.

A comparison was made of temperature variations in a bell furnace and in a pit retort furnace during the heat treating of small, flat springs made of beryllium copper (see Fig. 6). Both furnaces were rated at 30 kW. The load in each furnace weighed 90 kg (200 lb) and contained 55,000 to 60,000 springs. An exothermic gas, produced by a generator using an air-to-gas ratio of 6.75:1 (capacity, 10 m^3/h, or 350 ft^3/h), was used as the protective atmosphere. The composition of the atmosphere was 6.5% CO, 6% CO_2, 10% H_2, rem N_2, dew point was 2 °C (35 °F) after refrigeration (18 to 21 °C, or 65 to 70 °F, as generated).

Fig. 6 Temperature variations in two types of furnaces (Example 1). (a) Bell furnace. (b) Retort furnace

Salt baths can reduce total furnace time by up to 30%, compared to that required with atmosphere furnaces (Fig. 7). Salt baths are particularly valuable when the age-hardening time is of short duration and when the precise control of time at the aging temperature is required.

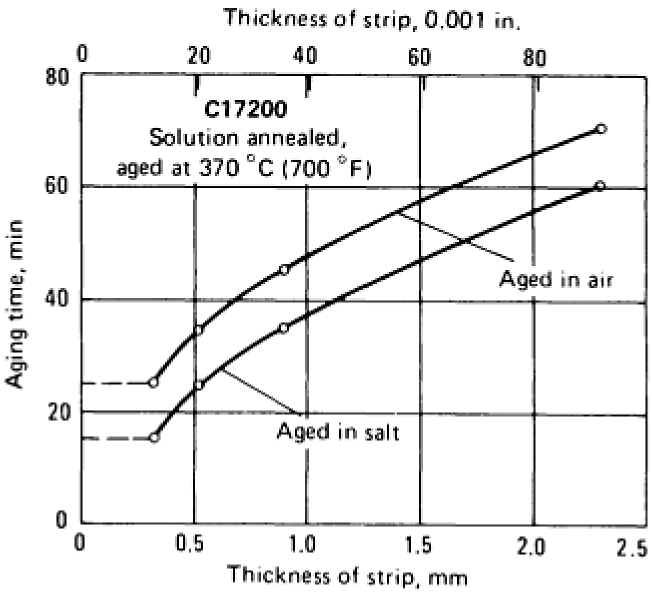

Fig. 7 Effect of metal thickness and heating medium on aging time required to develop maximum strength in C17200 strip

Commercially available nitrate-nitrite salt mixtures (40 to 50% sodium nitrate, remainder sodium or potassium nitrite) that melt at 143 °C (290 °F) are used for aging and stress relieving. All material to be heated in salt should be properly cleaned and dried before being immersed in the molten salt; any organic substance (such as oil or grease) will react violently with the nitrate-nitrite salt.

Protective Atmospheres

The selection of protective atmospheres for heat treating copper and copper alloys is influenced by the temperature used in the heat-treating process.

Heating above 705 °C (1300 °F). An exothermic atmosphere is the least expensive protective atmosphere for the heat treatment of copper alloys. The air-to-gas ratio is adjusted to produce a combusted gas that contains 2 to 7% H for use in muffle furnaces operating at 705 to 995 °C (1300 to 1825 °F). This atmosphere is used successfully for solution treating alloys such as beryllium coppers, chromium coppers, zirconium coppers, and copper-nickel-silicon alloys.

Usually, combusted gases are dried with a surface cooler, using tap water to keep the water-to-hydrogen ratio reducing throughout the heating and cooling cycle. It may be necessary to lower the dew point further by refrigerating the gas. If the furnace atmosphere is not sufficiently reducing, or if the muffle leaks air, a subscale, or internal oxidation of the hardening elements below the surface of the metal, results. Subscale formation can occur rapidly above 845 °C (1550 °F) if the atmosphere becomes oxidizing.

Dissociated ammonia is used primarily for annealing and brazing operations. The gas is very flammable and can explode if air enters the furnace while at an elevated temperature or if the furnace is improperly purged before reaching the elevated temperature.

Dissociated ammonia can be partly or completely burned with air to reduce cost and flammability. The hydrogen content can be controlled within a range of 1 to 24%, the remainder being nitrogen saturated with water vapor. Water must be removed to maintain a reducing atmosphere.

Hydrogen is highly reducing to copper oxide at elevated temperatures and is recommended for elevated-temperature bright annealing and brazing.

Commercial hydrogen contains about 0.2% O, which, if not removed, may cause internal oxidation of the reactive alloying elements in the copper.

When mixed with air, hydrogen is explosive at elevated temperature. Therefore, the furnace must be purged before being heated to high temperature, and air must not enter the furnace.

Heating below 705 °C (1300 °F). Combusted gas (lean exothermic atmosphere) is the most widely used protective atmosphere for the anneal of copper and copper alloys. Because of its low sulfur content, natural gas is the preferred fuel for the production of combusted gas. The air-to-gas ratio is adjusted to produce a hydrogen content of 0.5 to 1%. Combusted gas is dried before entering the furnace to prevent discoloration and staining of the metal by water vapor during the cooling cycle.

Steam is the most economical atmosphere for protecting copper alloys during annealing. Although the annealed metal is not as bright as when heated in a combusted-fuel-gas atmosphere, it is satisfactory for some applications. For products such as tightly wound coils of strip, steam can be used during the heating cycle, and combusted fuel gas can be used during cooling.

Inert gases, dissociated ammonia burned with air, and vacuum are more expensive and are not in common use for the annealing of copper alloys. A major disadvantage of vacuum is that heating and cooling are slow because heat is transferred by radiation only.

Copper-Beryllium Alloys

Because the solid solubility of beryllium in an α-copper matrix decreases as the temperature is lowered, beryllium-copper alloys are precipitation hardenable. Heat treatment typically consists of solution annealing, followed by precipitation hardening. Table 6 gives recommended schedules for the solution treating and precipitation hardening of the five major copper-beryllium alloys that are produced in wrought form. Optimum mechanical and physical properties for specific applications can be attained by varying these schedules, but the temperatures and times given in this table constitute the most conventional practice and typically provide maximum tensile strength. In addition, better age hardening characteristics can be obtained if the material is cold worked after the solution anneal.

Table 6 Solution treating and precipitation hardening of copper-beryllium alloys

Alloy	**Solution**[a]			Aging treatment		
	Temperature		**Time**[b] **h**	**Temperature**		Time, h
	°C	**°F**		**°C**	**°F**	
C17000	775-800	1425-1475	$\frac{1}{2}$-3	300-330	575-625	**1-3**
C17200	775-800	1425-1475	$\frac{1}{2}$-3	300-330	575-625	**1-3**

C17300	775-800	1425-1475	$\frac{1}{2}$-3	300-330	575-625	**1-3**
C17500	900-925	1650-1700	$\frac{1}{2}$-3	455-480	850-900	**1-3**
C17510	**900-925**	**1650-1700**	$\frac{1}{2}$**-3**	**455-480**	**850-900**	**1-3**

(a) All alloys are cooled immediately and rapidly from the solution-treating temperature. Thin sections such as strip can be cooled in circulating atmosphere; heavier sections require water quenching.

(b) Shorter times may be desirable to minimize grain growth, particularly for thin sections.

There is a wide variety of copper-base casting alloys (C81300 through C82800), in addition to the wrought copper-beryllium alloys, that contain beryllium. Appropriate solution-treating and aging schedules for these alloys are dictated by the levels of beryllium and other additives.

Solution Treating

Wrought copper-beryllium alloy mill products are generally supplied solution treated or solution treated and cold worked (Table 7). Material in these conditions can be fabricated without further heat treatment. Thus, solution treating is not typically a part of the fabricating process unless it is necessitated by a special requirement such as softening of the material for additional forming or is used as a salvage operation for parts that have been incorrectly heated for precipitation hardening.

Table 7 Typical conditions of copper-beryllium mill products

Temper	**Description**	Tensile strength before aging	
		MPa	ksi
TB00	Solution treated	480	**70**
TD01	Solution treated and cold worked to $\frac{1}{4}$ hard	550	**80**
TD02	Solution treated and cold worked to $\frac{1}{2}$ hard	625	**91**

In the quenched condition, copper-beryllium alloys are easily fabricated by standard production methods. Strip can be readily blanked, formed, deep drawn, or spun. Rod and bar respond to hot or cold forming, including forging, machining, and swaging. However, even though fully solution-annealed material is the softest form available, better age-hardening properties can be obtained if the material is cold worked after the final solution anneal. Therefore the alloy is often used

in one of the cold-worked tempers shown in Table 7. The selection of a proper temper for a particular application is based on the severity of cold forming and the mechanical property requirements.

Solution-treating temperature limits must be adhered to if optimum properties are to be obtained from the precipitation-hardening treatment. Solution treating below the specified minimum temperature results in insufficient solution of the beryllium-rich phase. This results in lower hardness after precipitation hardening (Fig. 8).

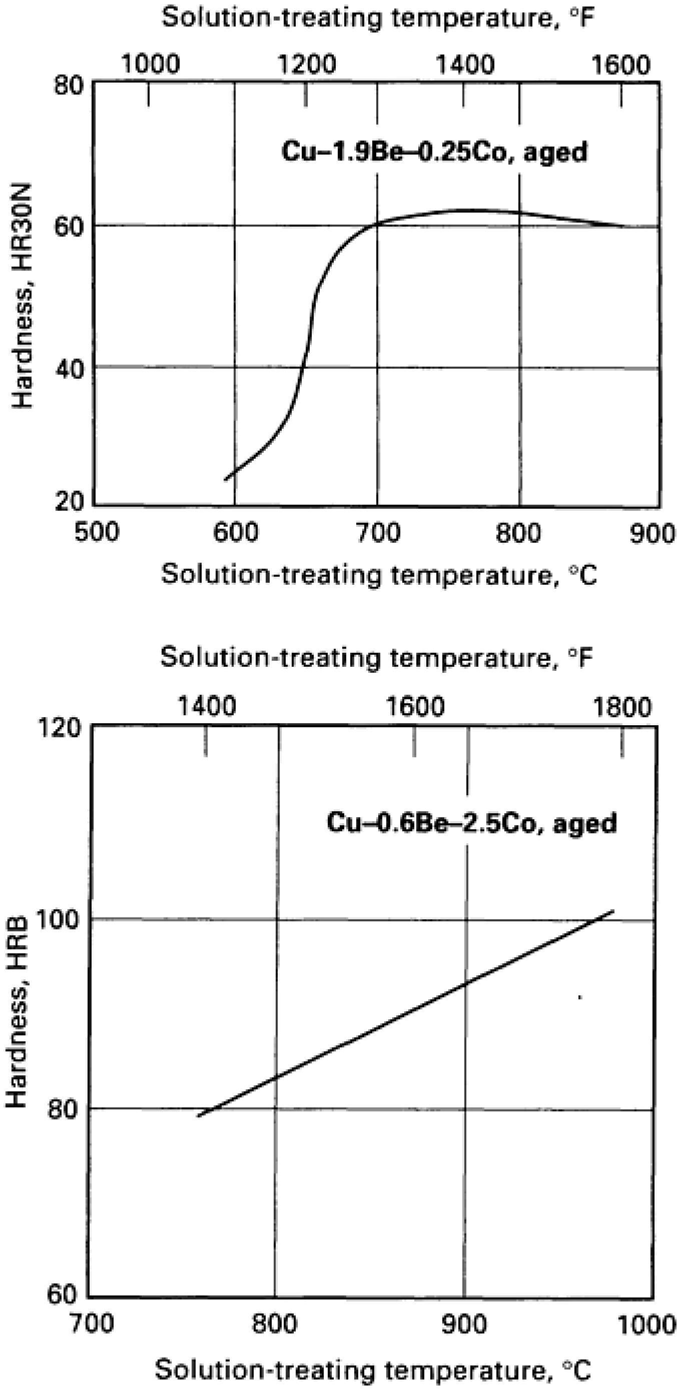

Fig. 8 Effect of solution-treating temperature on hardness of C17200 and C17500 after aging

Also, solution treating must be carefully controlled to produce the desired grain size, dimensional tolerances, and mechanical properties and to prevent oxidation. Exceeding the upper temperature limit causes grain coarsening in wrought material and overheating in wrought and cast materials. A coarse grain size impairs formability; overheating results in a brittle material that does not fully respond to precipitation hardening.

Effect of Solution-Treating Time. The time at the solution-treating temperature depends on the amount of beryllium-rich phase that must be dissolved. Solution of this phase must be complete to produce maximum strength after precipitation hardening.

In cast products, the as-cast structure usually contains a large amount of microsegregation within the dendritic pattern. Therefore, castings must be heated for a length of time sufficient to homogenize the structure. A minimum of 3 h at temperature is recommended for this purpose.

The solution treating of wrought material also removes the effects of cold working and permits additional forming. Some grain growth will occur during softening for additional forming because the solution-treating temperature is above the recrystallization temperature. Therefore, to minimize grain growth, excessive time at temperature must be avoided. It is recommended that wrought alloys be held at temperature 1 h for each inch or fraction of an inch of section thickness. The optimum amount of time for a specific application must be determined by mechanical testing and microscopic examination of the alloy.

Effect of Oxidation. When copper-beryllium alloys are solution treated in air or in an oxidizing atmosphere, two types of oxidation are encountered. A continuous and tenacious oxide surface layer forms on alloys with high beryllium contents. Low-beryllium alloys form a loosely adhering scale and are subject to internal oxidation.

The oxide layer on high-beryllium alloys does not significantly affect the mechanical properties of the precipitation-hardened material, but it is abrasive and causes severe wear of tools and dies if not removed. The oxidation of low-beryllium alloys not only has an abrasive effect, it decreases mechanical properties. This is caused by the surface layer of internal oxidation, which reduces the effective section thickness of the material. For both types of alloys, oxides may be removed by chemical or abrasive cleaning methods.

Quenching is a critical phase of the solution-treating process. Successful treatment requires that the material be quenched immediately, and at the highest possible rate, after being removed from the furnace. Any time lapse during transfer from the furnace to the quenching medium permits some cooling and causes precipitation. Precipitation is rapid at elevated temperatures and its occurrence significantly affects the properties obtained during subsequent precipitation hardening. The maximum allowable delay before quenching depends on the mass of the load, the size of the parts, and the transfer equipment. Mechanical testing and microscopic examination of the structure should be used to evaluate the effectiveness of the quenching operation.

Water quenching is the most common method of retaining the solid-solution condition in both wrought and cast products; however, because of their shape, some castings may crack as the result of the rapid cooling. Such castings may be quenched in oil or forced air; however, the slower cooling rates may cause some precipitation. Thin-gage strip is typically cooled in forced air.

Precipitation Hardening

The cold working of solution-treated copper-beryllium alloys influences the strength attainable through subsequent aging; the greatest response to aging occurs in material in the cold-rolled hard temper. In general, work hardening offers no advantage beyond the hard temper because formability is poor and control of the precipitation-hardening treatment for maximum strength is critical. For some applications, however, wire is drawn to higher levels of cold work prior to precipitation hardening.

Table 8 lists the properties typically specified for mill products of the common copper-beryllium alloys, and Fig. 9 shows the time required to develop maximum tensile strength in one of these alloys aged at various temperatures. The aging times in Fig. 9 vary slightly from those given in Table 8 for the same alloy; the latter are primarily for acceptance-test purposes.

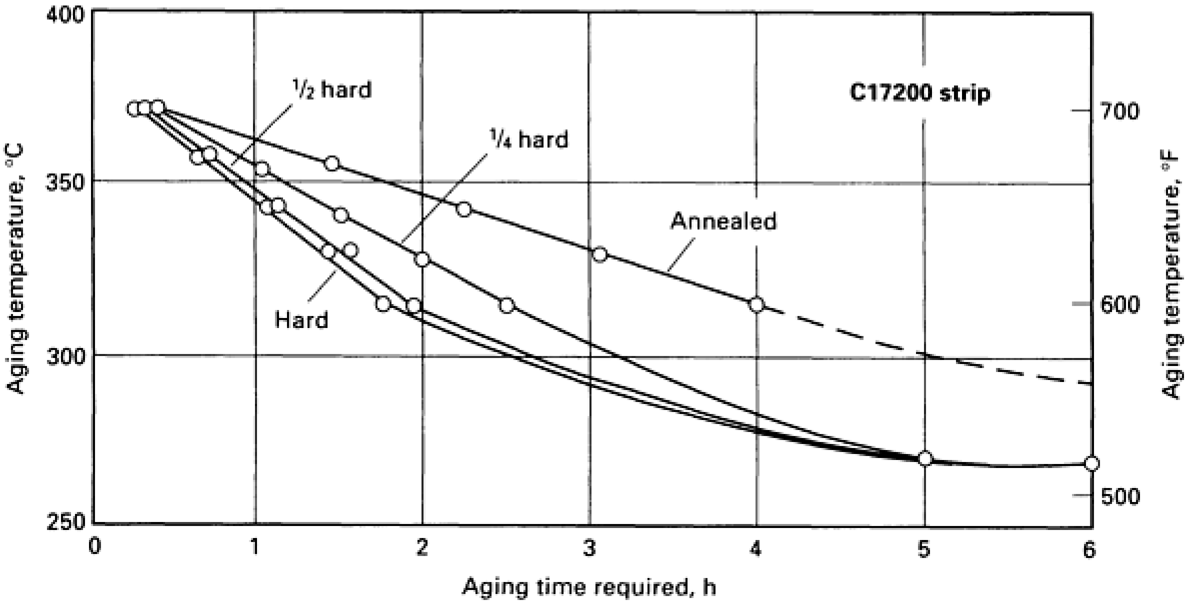

Fig. 9 Time-temperature relationships in aging of C17200 strip, showing aging time required for the development of maximum strength in annealed, $\frac{1}{4}$ hard, $\frac{1}{2}$ hard, and hard C17200 strip aged at various temperatures in a recirculating-air furnace

Special combinations of properties can be obtained by varying either the aging time or the aging temperature. Table 9 shows the age-hardening response from underaging to overaging for cold-rolled material in various tempers. As tensile strength increases, elongation decreases and does not recover substantially with overaging, but electrical conductivity continues to increase. The response of alloy C17200 (1.9Be-0.2Co + Ni) at other aging temperatures within the hardening range (290 to 400 °C, or 550 to 750 °F) are similar to the response at 370 °C (700 °F), but the corresponding time cycles vary. Recommended precipitation-hardening cycles for solution-treated copper-beryllium castings are given in Table 10.

Table 9 Effects of special precipitation-hardening treatments on mechanical properties and electrical conductivity of Cu-1.9Be strip

Effect of Temperature. The close control of temperature is critical in the conventional aging of copper-beryllium alloys. As indicated by the data in Tables 8 and 9, a change in temperature affects the time required for the development of maximum properties. Also, the higher temperatures can result in lower property values. Normal commercial control of ±6 °C (±10 °F) is adequate for temperatures in the range from 315 to 370 °C (600 to 700 °F).

Problems involving temperature usually arise when test data are translated into production control data. A strip specimen of the material tested at the mill may just meet the minimum specification requirements; however, when the fabricator heat treats a large mass of parts made of the same material, tests may indicate properties below the minimum requirements. The low properties may result from heat treating too large a mass of parts relative to the capacity of the furnace, inadequate time at the proper temperature, or the use of a higher temperature to gain production speed or to obtain fixture conformity when the parts are in fixtures.

Effect of Grain Size. The effect of grain size on the properties of heat-treated material is less significant for copper-beryllium alloys than for solid-solution alloys such as brass and phosphor bronze. The relatively high temperatures required for solution treating copper-beryllium alloys usually override the effects of cold work and time at temperature. Low solution-treating temperatures will result in a fine grain size, but, if the temperature is too low to dissolve the beryllium-rich phase, the response to aging will be affected adversely and the benefits obtained from the fine grain size will be nullified. For this reason, grain sizes below about 0.015 mm (0.0006 in.) are not practical for most beryllium-

copper products, regardless of dimensions. With normal commercial practice, and depending on the product, the grain size of solution-treated material will range from about 0.015 to 0.060 mm (0.6 to 2.4 mils).

Fixturing for Close Tolerances. Excellent dimensional accuracy can be achieved by properly supporting beryllium-copper parts during aging. Usually, overaging is necessary to hold close tolerances. Fixture design should be based on certain principles:

- Fixtures should be of minimum weight
- Excessive clamping pressure should be avoided, to prevent stripping of clamping-screw threads and warping of fixtures
- Parts should be held only at critical locations
- A maximum number of parts should be held by a minimum number of clamping screws
- Design should minimize warping of the fixture, maximizing its service life
- When the configuration of the part permits, the fixture should be designed so that parts can be stacked. Often parts having no more than two planes can be stacked (see Fig. 10), provided that no burrs are present

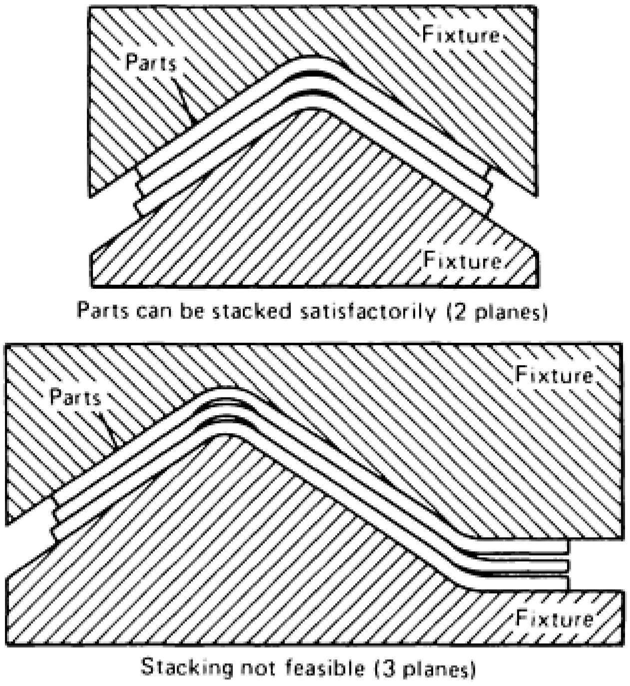

Fig. 10 Parts that can and those that cannot be stacked in fixtures for the control of dimensional tolerances during aging

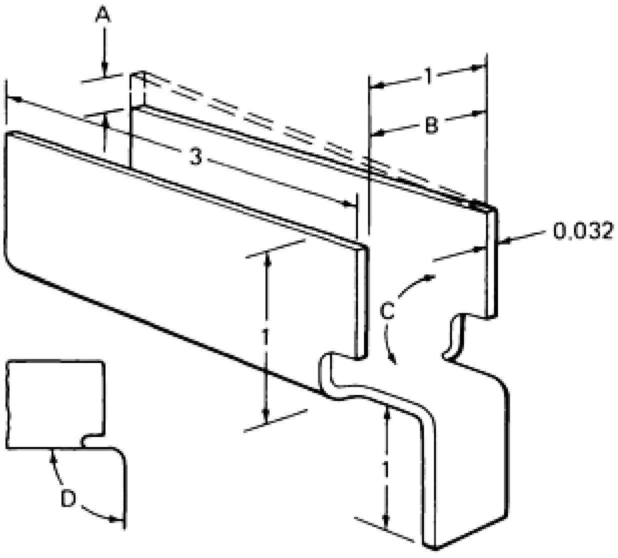
An understanding of the behavior of beryllium-copper alloys during the hardening treatment is helpful in the design and use of fixtures for parts with a controlled gap or opening. These may be U-shaped parts, circular parts, or clips of various designs. During heating for hardening, the material will move in the direction in which it was plastically formed or elastically deflected. If both conditions occur before hardening, movement due to the elastic effect will prevail. These phenomena may be illustrated by the examples below.

Example 2: Reduction in Dimensional Variation with Fixturing.

A comparison was made of the dimensional variations that occurred during the aging of solenoid guides heated as loose pieces and as fixtured pieces. The fixture that was used supported, with adequate pressure, all inside and outside surfaces of the part. Although the total cost of aging the guides as fixtured pieces was nearly two and a half times the cost of aging them as loose pieces (total cost per piece, based on the aging of 100 000 pieces per year), a significant improvement (reduction) in dimensional variation was achieved by the use of fixtures (Table 11).

Table 11 Dimensional variations in beryllium-copper solenoid guides aged with and without fixtures (Example 2)

Dimension	Dimensional variation(a)	
	Loose pieces	Fixtured pieces
A(b)	$\leq \frac{3}{16}$ in.	$\frac{1}{32}$ **in. max**
B	$-\frac{1}{8}$ to $\frac{1}{16}$ in.	**±0.010 in.**
C	-4 to 2°	$\pm\frac{1}{2}$ °
D	**-4 to 2°**	$\pm\frac{1}{2}$ °



(a) Assuming no deviations from the die operation.

(b) Twist in 3 in.

Example 3: Fixturing and Aging Procedure for Dimensional Control of a Beryllium-Copper Spring Clip.

Spring clips like the one shown in Fig. 11 were press formed to a slightly undersized inside diameter (24.9 to 25.2 mm, or 0.980 to 0.990 in.) so that they would fit snugly on a mandrel 25.4 ± 0.03 mm (1 ± 0.001 in.) in diameter. However, during aging for $\frac{1}{2}$ h at 350 °C (660 °F), the metal moved in the direction of elastic deflection, which caused the clips to be loose on the mandrel. Because precipitation hardening of beryllium-copper is a cumulative time-temperature reaction, the hardening treatment can be interrupted. Therefore, the clips (without being placed on the mandrel) were partially aged

for 5 min at 350 °C (660 °F) (decreasing the original dimension to 24.8 to 25.0 mm, or 0.975 to 0.985 in.) and then were placed on the mandrel and aged at the same temperature for the remaining 25 min.

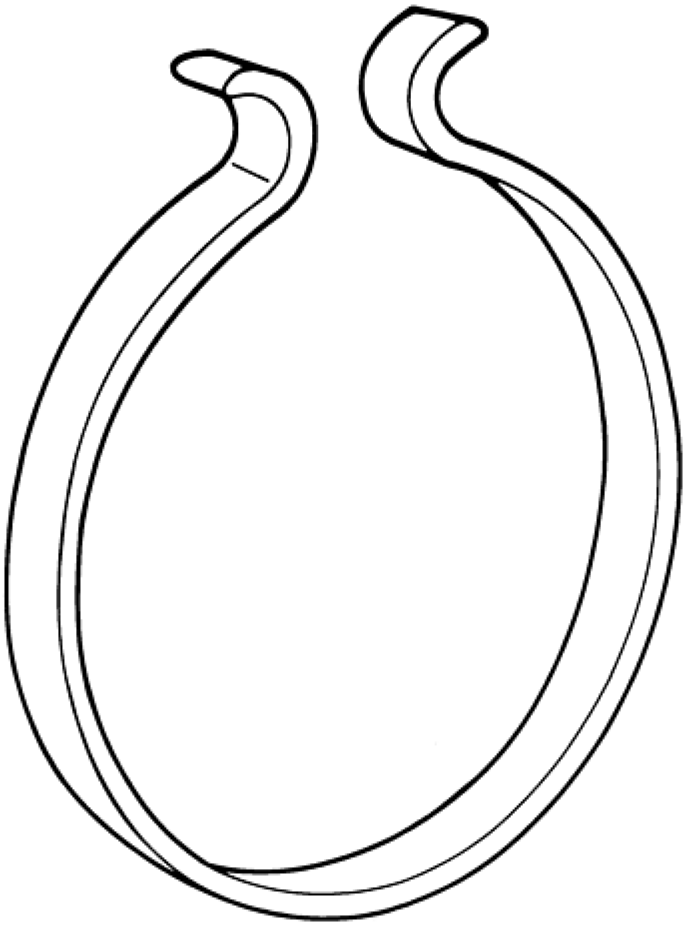


Fig. 11 Spring clip representing a type of beryllium-copper part that should be partially aged without a fixture and then placed on a mandrel for final aging, for control of diameter

Following this aging treatment, none of the clips was larger than the diameter of the mendrel; the actual final dimension was governed by the time and temperature of aging, that is, by the amount of stress relief that occurred.

Interrupted Aging. The selection of the time and temperature for the first step of the interrupted aging sequence (Example 3, above) is important but not critical. If the time is inadequate, the direction of movement will not be established; if excessive, there will be insufficient time for heating the parts on the fixture to allow enough stress relief for close conformity. Usually the duration of the preliminary treatment should be about 15% of the total aging time. Allowance must be made for the mass effect of the load on the time required for it to reach furnace temperature. Also, interrupted aging procedures can be used to restrict increases in the outside diameters of various parts.

Inspection and Quality Control. In most instances, the completeness of aging can be verified by hardness testing. Exceptions are the tension testing of specimens taken from large parts and simulated service testing to determine elastic performance. Figure 12 is an example of variations observed from tensile testing.

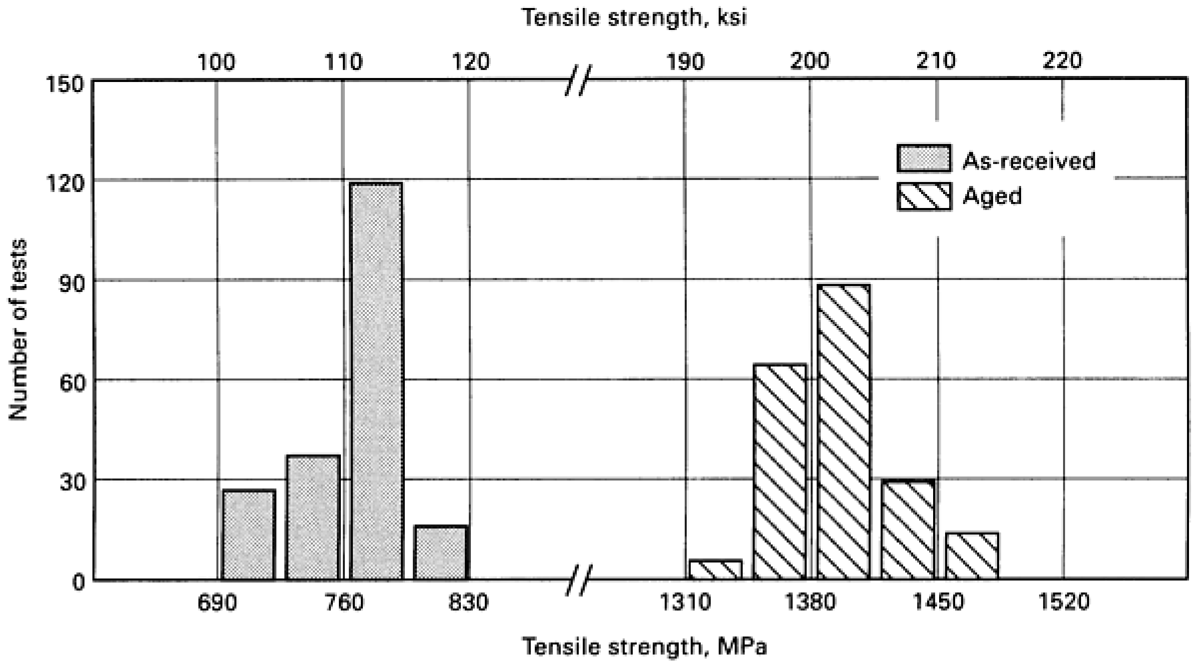

Fig. 12 Variation in tensile strength of hard C17200 strip after aging. The strip was 0.17 to 0.19 mm (0.0065 to 0.0075 in.) thick and was aged 3 h at 315 °C (600 °F). The number of tests of each group was 200.

Hardness measurements should always be made using the method and load most suitable for the thickness of the material and the normal level of hardness expected. Table 12 indicates suggested methods for testing various thicknesses of a hardened beryllium-copper alloy. Variations obtained with heat-treated parts and with strip are presented in the examples below.

Table 12 Suggested methods for measuring the hardness of heat-treated C17200

Thickness		Hardness test method	Load, kg
mm	in.		
0.03-0.08	0.001-0.003	Diamond pyramid	**0.2**
0.08-0.38	0.003-0.015	Diamond pyramid	**0.5**
0.38-0.51	0.015-0.020	Rockwell superficial 15N	**15**
0.51-1.02	0.020-0.040	Rockwell superficial 15N	**30**

Example 4: Hardness Variations in Beryllium-Copper Springs.

Terminal springs made of a beryllium-copper alloy of the composition 0.8 to 1% Be, 0.85% (max) Ni + Co + Fe, 3% (max) Zn + Sn were solution annealed and then aged for 5 h at 343 ± 6 °C (650 ± 10 °F) in a batch-type recirculating-air furnace (Fig. 13). The furnace load consisted of 280,000 pieces. Hardness tests were conducted on specimens of strip

material representative of the parts. Specifications required a hardness of 70 to 75 HRI5N. Results of hardness tests on 41 production lots within a 3-month period are presented in Fig. 13.

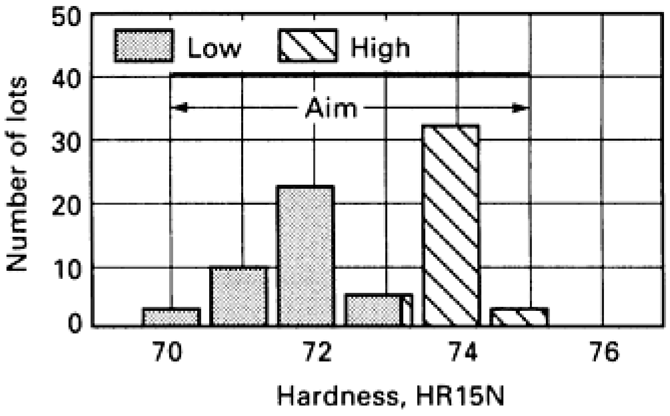

Fig. 13 Variation in hardness for 41 lots of heat-treated beryllium-copper terminal springs tested over a three-month period. High and low values in each lot are plotted.

Example 5: Hardness Variations in a Beryllium-Copper Spring Receptacle.

Spring contact receptacles stamped from $\frac{1}{4}$ hard beryllium-copper strip (alloy C17200) were aged in a salt bath at 300 °C (575 °F) for 30 min. The salt pot, 915 × 840 × 760 mm (36 × 33 × 30 in.), contained 1090 kg (2400 lb) of nitrate-nitrite salt (see Fig. 14).

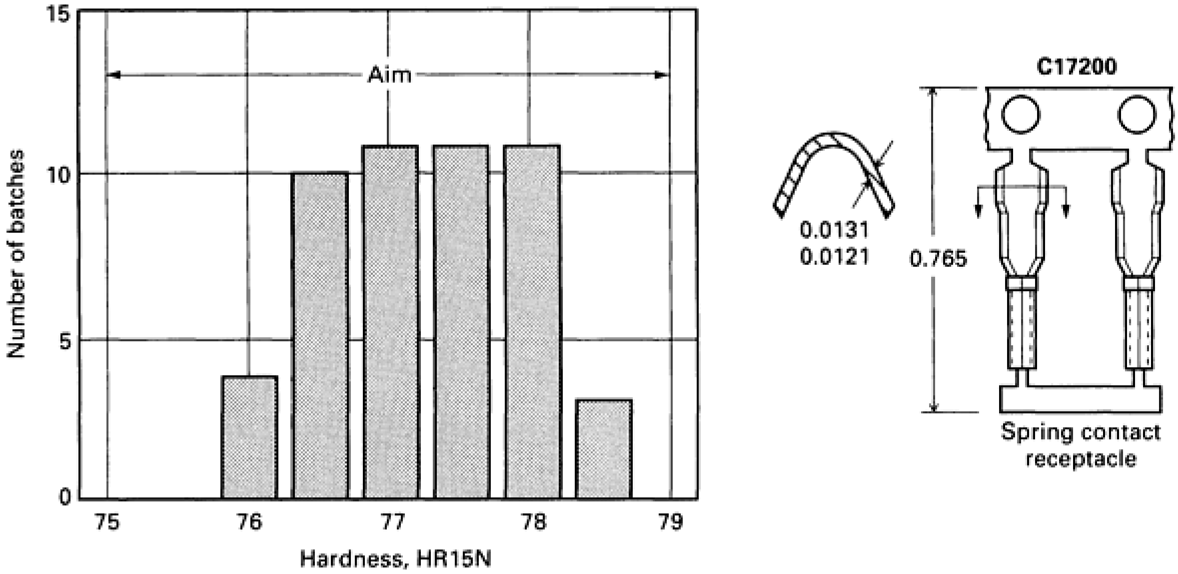

Fig. 14 Variation in hardness for 50 batches of aged spring contact receptacles stamped from $\frac{1}{4}$ hard C17200 strip

A strip of about 1000 of these parts was wound onto a birdcage reel 265 mm (10 $\frac{1}{2}$ in.) in diameter and 305 mm (12 in.) wide. Each receptacle weighed about 0.6 g (0.02 oz); therefore, the total weight of the receptacles on each reel was about 565 g (20 oz). Each reel weighed about 0.9 kg (2 lb), and one furnace load consisted of eight reels.

Specified hardness for these parts was 75 to 79 HR15N. Figure 14 shows the variation in hardness for 50 batches.

Copper-Chromium Alloys

Copper-chromium alloys of 0.5 to 1.0% Cr are solution treated, in molten salt or in controlled-atmosphere furnaces to avoid scaling, at 980 to 1010 °C (1800 to 1850 °F) and rapidly quenched. Solution-treated chromium copper is soft and ductile; therefore, it can be cold worked in a manner similar to that used for unalloyed copper.

After being solution treated, the material may be aged for several hours at 400 to 500 °C (750 to 930 °F) to produce special mechanical and physical properties. A typical aging cycle is 4 h or more at 455 °C (850 °F).

Typical effects of heat treatment and cold work on the properties of chromium-copper are shown in Table 13. The hard drawn specimens were obtained by reducing the cross-sectional area of solution-annealed specimens by approximately 40%.

Table 13 Typical effects of heat treatment and cold work on properties of Cu-1% Cr alloys

Copper-Zirconium Alloys

The solution treatment of zirconium-copper of the composition 99.7% Cu (min), 0.13 to 0.30% Zr consists of heating to 900 to 980 °C (1650 to 1795 °F) and quenching in water. The material may then be precipitation hardened for 1 to 4 h at 500 to 550 °C (930 to 1020 °F). If cold working is done prior to aging, the aging temperature is reduced to 370 to 480 °C (700 to 900 °F) for 1 to 4 h.

Time at the solution-treating temperature should be minimized in order to limit grain growth and possible internal oxidation by a reaction of the zirconium with the furnace atmosphere. Because the solution and diffusion of the zirconium occur rapidly at the solution-treating temperature, holding at temperature is not required.

Optimum mechanical properties and resistance to softening are developed with a maximum solution of zirconium. If material containing 0.15% Zr or more is heated above 980 °C (1795 °F), the Cu_3Zr phase will begin to melt. A slight amount of melting will not affect mechanical properties, but if excessive melting occurs, the ductility of the alloy will decrease.

Normally, as the solution temperature is increased from 900 to 980 °C (1650 to 1795 °F), the aging temperature should also be increased to maintain high electrical conductivity. Aging treatments that produce the best combination of mechanical properties and electrical conductivity are:

Condition	**Temperature**		Time ,h
	°C	**°F**	
Solution treated			
At 900 °C (1650 °F)	500	930	**3**
At 900 °C (1650 °F) and cold worked	400	750	**3**
At 980 °C (1795 °F)	550	1020	**3**

The increase in the strength of zirconium-copper depends primarily on cold working. Although aging results in some increase in strength, its chief effect is to increase electrical conductivity. The properties developed by various combinations of heat treatment and cold working are given in Table 14.

Table 14 Effect of heat treatment and cold work on properties of copper-zirconium alloy C15000

Miscellaneous Precipitation-Hardening Alloys

Other alloys that can be age hardened are the nickel-tin bronze alloys C94700 and C94800, copper-nickel-beryllium alloy C96600, and the complex, special alloys C99400 and 99500. The solution-treating and precipitation-hardening treatments for these alloys are shown in Table 15.

A protective atmosphere of exothermic gas or dissociated ammonia is recommended during the aging of these alloys to produce bright surfaces. Parts heated in gas-fired or oil-fired furnaces in which the products of combustion are used as a protective atmosphere may tarnish slightly and require cleaning. Aging in an oxidizing atmosphere results in scaling.

Alloys C19000 and C19100 (Cu-4Ni-0.25P) also respond to precipitation hardening. The alloys are solution treated at 705 to 790 °C (1300 to 1450 °F). A reducing or neutral atmosphere should be used to prevent internal oxidation, especially on thin sections. Water quenching is preferred, although rapid air cooling may be adequate for separate small parts. Precipitation hardening is accomplished by aging the alloy at 425 to 480 °C (800 to 900 °F) for 1 to 3 h. While annealing is required to facilitate cold working prior to aging, temperatures as low as 620 °C (1150 °F) followed by normal air cooling are adequate.

Spinodal-Hardening Alloys

Spinodal structures are composed of a fine, homogeneous mixture of two phases that form by the growth of composition waves in a solid solution during a suitable heat treatment. The phases of the spinodal product differ in composition from each other and from the parent phase but have the same crystal structure as the parent phase. The fineness of spinodal structures is characterized by the distance between regions of identical composition, which is of the order of 50 to 1000 Å.

The conditions for the formation of a spinodal structure are thermodynamic and diffusional; the particular alloy system must have a miscibility gap (either stable or metastable), and the atoms of the two component metals must possess sufficient mobility at the heat-treating temperature. A phase diagram of a hypothetical binary alloy system with a stable miscibility gap is shown in Fig. 15. An alloy of composition C_0 that is homogenized in the single-phase α region and then held within the spinodal region is unstable to composition variations and will transform spontaneously to the two product phases α_1 and α_2 without requiring nucleation. If an alloy decomposes within the spinodal region by a diffusional process that allows composition variations to increase in magnitude, it is said to decompose spinodally. The resulting spinodal structures refer to phase mixtures that are derived from a particular kinetic process governing the initial stages of phase separation. The chemical spinodal line shown in Fig. 15 is not a phase boundary but a demarcation indicating a difference in thermodynamic stability.

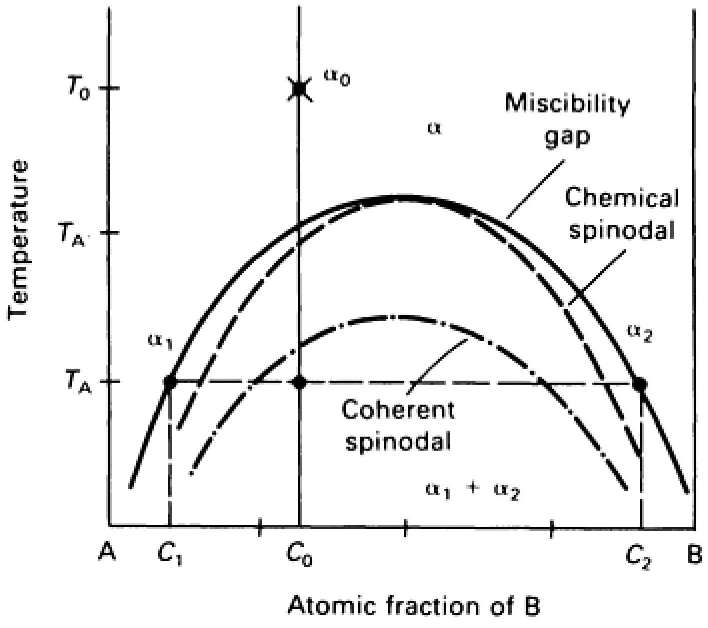

Fig. 15 Phase diagram of a binary alloy system that contains a miscibility gap in the solid state. An equilibrium structure for alloy C_0 at temperature T_A would contain two α phases of compositions C_1 and C_2. Spinodal decomposition can occur in the temperature-composition range below the chemical-spinodal line, which is the locus of points defined by the inflection points of the isothermal free energy (*G*) composition curves ($\partial^2 G/\partial C^2 = 0$).

The spinodal reaction is a spontaneous unmixing or diffusional clustering distinct from classical nucleation and growth in metastable solutions. This different kinetic behavior, which does not require a nucleation step, was first described by Gibbs in his treatment of the thermodynamic stability of undercooled or supersaturated phases. At small undercoolings or low supersaturations ($T_{A'}$), the solution is metastable; the appearance of a second phase requires relatively large localized compositional fluctuations. This is the classical nucleation process, giving rise to so-called critical nuclei, which can grow spontaneously. As the particles of the new phase grow by diffusion, the matrix composition is adjusted toward equilibrium. At large supersaturations (T_A), the solution is unstable, and the two-phase mixture gradually emerges by the continuous growth of initially small amplitude fluctuations (Fig. 16). The rate of reaction is controlled by the rate of atomic migration and the diffusion distances involved, which depend on the scale of decomposition (undercooling).

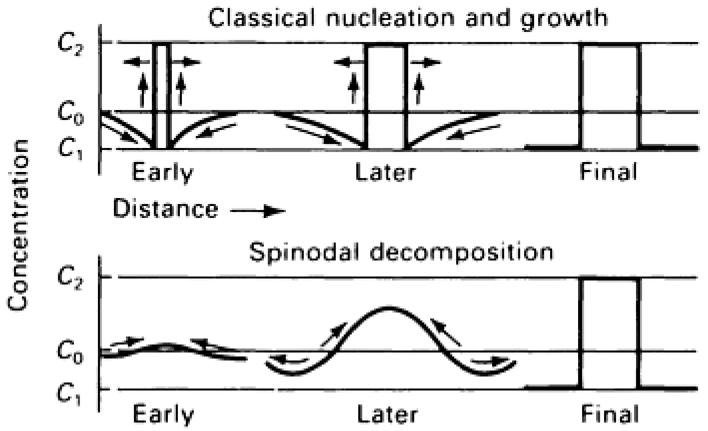

Fig. 16 Two sequences for the formation of a two-phase mixture by diffusion processes: nucleation and growth, and spinodal decomposition

The essential features of the spinodal process can be understood by considering this diffusional clustering as the inverse of the homogenization of a nonuniform solid solution exhibiting a sinusoidal variation of composition with distance. Long wavelength fluctuations grow sluggishly because of the large diffusion distances; short wavelength fluctuations are suppressed by the so-called gradient, or surface energy, of the diffuse or incipient interfaces that evolve during phase separation. Therefore, the microstructure that develops during spinodal decomposition has a characteristic periodicity that is typically 2.5 to 10 nm (25 to 100 Å) in metallic systems.

The heat treatment that causes the spinodal decomposition of a hypothetical alloy of composition C_0 (Fig. 15) is:

- Homogenize at a temperature above the miscibility gap, such as T_0, so that only statistical variations in composition exist within the specimen
- Cool rapidly to a temperature within the spinodal region, such as T_A, and hold at that temperature, or continuously cool the specimen from T_0, to room temperature

Table 16 lists the recommended solution treatment for the copper-nickel-chromium and copper-nickel-tin spinodal-hardening alloys. It is important to maintain control within the limits shown in order to obtain the proper heat-treating response in the subsequent spinodal aging treatment. Exceeding the upper limit may result in excessive grain growth in wrought materials, which could impair formability in the solution-annealed condition. Overheating cast material may cause incipient melting, resulting in brittle material that does not respond to spinodal hardening, particularly in the copper-nickel-tin alloys. Solution treating below the minimum temperature results in incomplete solution and failure of the material to harden fully during the spinodal aging treatment.

Table 16 Recommended solution-heat-treating temperatures and times for spinodal alloys

Alloy	**Alloy number**	**Solution-heat-treating temperature**		Time at temperature, h
		°C	**°F**	
Cu-30Ni-3Cr	C71900	900-950	1650-1740	$\frac{1}{2}$ **-2**
Cu-4Ni-4Sn	C72600	700-760	1300-1400	$\frac{1}{2}$ **-2**
Cu-9Ni-6Sn	C72700	730-790	1350-1450	$\frac{1}{2}$ **-2**
Cu-10Ni + 8Sn + 0.2Nb	C72800	805-845	1480-1550	$\frac{1}{2}$ **-2**

Wrought materials of some of these alloys can be extensively cold worked, with up to 90% reduction, after an effective solution treatment and quench. Solution anneals used between working schedules must be controlled toward the lower end of the temperature range and the minimum holding times to minimize grain growth because the solution temperature is above the recrystallization temperature. However, wrought alloys should be solution treated for approximately $\frac{1}{2}$ h for each inch of section thickness (or fraction thereof).

Homogenization. Cast microstructures of spinodal-hardening alloys generally require homogenization to encourage a uniform distribution of hardening elements and adequate response to the hardening treatments. The C71900 alloy may be homogenized by a prolonged solution-treating temperature. The copper-nickel-tin alloys have a tendency to develop porosity at higher temperatures, and therefore homogenization is best accomplished by first heating the alloys to 725 °C (1335 °F) and holding long enough to spheroidize the γ phase (3 to 12 h). The temperature is then increased to the regular solution temperature in preparation for the quench.

Oxidation. When spinodal copper-nickel-tin alloys are solution treated in air or oxidizing atmospheres, oxidation is encountered, which can be extremely abrasive to tools although it will not substantially affect the mechanical properties of the spinodal-hardened material. The oxide generally does not penetrate far below the surface of these alloys, and it can be removed by mechanical, chemical, or abrasive cleaning methods.

Quenching is a critical step of the solution process for copper-nickel-tin alloys. Successful heat treating requires that the material be quenched at the highest possible rate from the solution-treating temperature. It is therefore necessary to provide both rapid transfer from furnace to quench tank and an efficient quenching medium. Delays sufficient to cause the loss of temperature before the quench could allow the copper-nickel-tin intermetallic γ phase to form, reducing the effectiveness of the entire heat treatment. The quenching medium, which is generally water, must be sufficiently cold and agitated to maintain a rapid cooling rate to below the 200 °C (400 °F) level to ensure that no premature spinodal hardening occurs.

In some circumstances, particularly with the low-tin alloys (C72600 and C72700), oil, air, or cold-gaseous-medium quenching may be used for small parts or very thin sections, but a careful evaluation of these methods should be conducted to ensure the adequacy of the quench. Both mechanical testing of fully treated materials and metallographic examination of the microstructure should be employed to evaluate the quenching practice. The overall cooling rate of the quenching of spinodal-hardening C71900 (copper-nickel-chromium) alloy is somewhat less critical, but it is equally important to begin the quench at a temperature above the 900 °C (1650 °F) temperature.

Spinodal Hardening (Aging). Table 17 gives typical aging treatments and some resultant properties of various spinodal-hardening alloys. The effect of cold working between the solution quench and aging steps is also given for the copper-nickel-tin alloys. The copper-nickel-chromium (C71900) alloy can be hardened by slow cooling from the solution-treating (full annealing) range through 760 °C (1400 °F) or by a spinodal aging treatment in the 425 to 760 °C (800 to 1400 °F) range after a solution treatment. Slow cooling from solution temperature tends to produce slightly greater ductility.

Table 17 Typical strengths and recommended aging times for various spinodal alloys

(a) Offset shown in parentheses

The Cu-Ni-Sn alloys are hardened by treating in the rather narrow temperature range of 350 to 360 °C (660 to 680 °F). The development of the optimum properties requires the careful control of temperature and time at temperature. The use of hardness alone to evaluate results may not be adequate because high hardness may be maintained where excessive aging causes a decrease in elastic properties. Variations in tensile properties of 70 to 100 MPa (10 to 15 ksi) are possible without a significant hardness change.

Microduplexing. The copper-nickel-tin spinodal alloys can be treated using a combination of cold working and heat treatment called microduplexing. The alloys are cold worked to significant reductions (typically 40 to 60%) and given a partial solution treatment below the single-phase boundary, typically at 725 °C (1335 °F). The alloy is then aged at the higher spinodal-hardening temperature level of 425 °C (800 °F) for an extended time. The higher aging temperature is used to keep the aging time within reason, as microduplex age hardening takes place much more slowly than full spinodal hardening. This treatment results in moderately high tensile properties and significantly greater ductility. The curves in Fig. 17 show the effect of the microduplex treatment in comparison to conventional spinodal treatment using a 425 °C (800 °F) age.

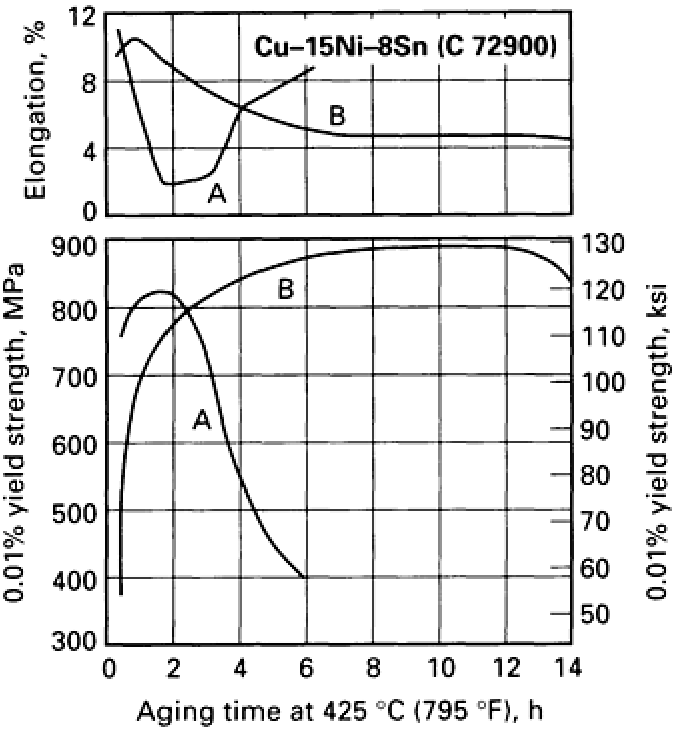

Fig. 17 Aging response of Cu-15Ni-8Sn (C72900) solution treated below the single-phase boundary (microduplexed) and above the single-phase boundary. Treatments prior to aging: A, solution treated above the single-phase boundary at 825 °C (1520 °F) for 30 min and water quenched; B (microduplexed), solution treated below the single-phase boundary at 725 °C (1340 °F) for 1 h and water quenched

Effect of Grain Size. The temperatures required for solution treatment are well into the recrystallization/growth range for spinodal-hardening alloys. The normal grain size obtained in properly treated wrought products is in the 0.010 to 0.090 mm (0.0004 to 0.0035 in.) range, but coarser grain sizes have been used without adverse results. Maintaining low solution temperatures in an attempt to minimize grain growth is good practice, but is second in importance to ensuring a complete solution treatment and adequate quench. An extremely fine grain size (2 to 4 μm) may be produced in the microduplexing treatment of copper-nickel-tin alloys because of the much lower solution-treating temperature and the nucleating effects of undissolved γ phase particles.

Fixturing in Close Tolerances. Excellent dimensional reproducibility can be achieved without fixturing during heat treatment. This is because the spinodal alloys do not undergo a crystallographic change during hardening. The chemical segregation (spinodal decomposition) is not accompanied by a second phase that can cause distortion during the aging process. Therefore, stability is greatly increased over that of precipitation-hardening alloys. Fixturing may nonetheless be necessary for extremely tight dimensional control, but this is rare.

Copper-Aluminum (Aluminum Bronze) Alloys

The microstructures and consequent heat treatabilities of aluminum bronzes vary with aluminum content much the same as these characteristics vary with carbon content in steels. Unlike steels, aluminum bronzes are tempered above the normal transformation temperature, typically in the range from 565 to 675 °C (1050 to 1250 °F). In the selection of

tempering temperatures, consideration must be given to both required properties and the hardness obtained upon quenching. Normal tempering time is 2 h at temperature. Moreover, heavy or complex sections should be heated slowly to avoid cracking. After the tempering cycle has been completed, it is important that aluminum bronzes be cooled rapidly using water quenching, spray cooling, or fan cooling. Slow cooling through the range from 565 to 275 °C (1050 to 530 °F) can cause the residual tempered martensitic β phase to decompose, forming the embrittling α-β eutectoid. The presence of appreciable amounts of this eutectoid structure can result in low tensile elongation, low energy of rupture, severely reduced impact values, and reduced corrosion resistance in some media. For adequate protection against detrimental eutectoid transformation, cooling after tempering should bring the alloy to a temperature below 370 °C (700 °F) within about 5 min, and to a temperature below 275 °C (530 °F) within 15 min. Normally, the danger of eutectoid transformation is much lower in nickel-aluminum bronzes, and these alloys can be air cooled after tempering.

The normal precautions used in the heat treating of steel have been found to be applicable to aluminum bronze, with critical cooling rates being somewhat lower than those for steel. Soaking time should be at least 45 min at temperature, and longer times may be used without fear of excess surface oxidation. Oil quenching is used on heavy, complex sections to avoid quench cracking, particularly in nickel-aluminum bronzes such as C63000.

Alpha-aluminum bronzes are those aluminum bronzes that contain less than 9% Al, or less than 8.5% Al with up to 3% Fe. They are essentially single-phase alloys, except for fine iron-rich particles in those alloys that contain iron. For α-aluminum bronzes, effective strengthening can be attained only by cold work, and annealing and/or stress relieving is the only heat treatment of practical use. The most prevalent alloys of this group are C60600, C61000, C61300, and C61400. In addition, alloys containing up to 9.6% Al, with microstructures containing small amounts of β phase at high temperatures, have such limited heat treatability that they, too, can be hardened only by cold work.

Annealing of α -aluminum bronzes is carried out at temperatures from about 540 to about 870 °C (1000 to 1600 °F), with the iron-containing alloys requiring temperatures nearer the high end of this range. Alloys of intermediate composition (containing small amounts of β phase), such as C61900, are normally annealed at 595 to 650 °C (1100 to 1200 °F). Figure 18 presents annealing curves for typical α-aluminum bronze alloys C61300 and C61400.

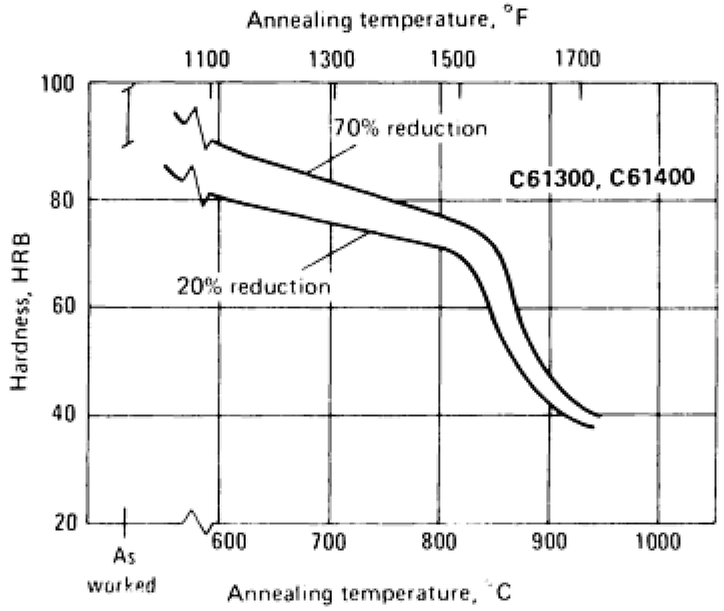

Fig. 18 Annealing curves for cold-reduced α-aluminum bronzes. Time at annealing temperature, 1 h

Complex α-β aluminum bronzes are those aluminum bronzes whose normal microstructures contain more than one phase to the extent that beneficial quench and temper treatments are possible. These copper-aluminum alloys, with and without iron, are heat treated by procedures somewhat similar to those used for the heat treatment of steel and have isothermal transformation diagrams that resemble those of carbon steels. For these alloys, the quench-hardening treatment is essentially a high-temperature soak intended to dissolve all of the a phase into the β phase. Quenching results in a hard room-temperature β martensite structure, and subsequent tempering reprecipitates fine α needles in the structure, forming

a tempered β martensite. Table 18 gives typical tensile properties and hardnesses of α-β aluminum bronzes after various stages of heat treatment.

Table 18 Typical heat treatments and resulting properties for complex (α-β) aluminum bronzes

Heat Treating of Magnesium Alloys

Revised by Archie Stevenson, Magnesium Elektron, Inc.

Introduction

MAGNESIUM ALLOYS usually are heat treated either to improve mechanical properties or as a means of conditioning for specific fabricating operations. The type of heat treatment selected depends on alloy composition and form (cast or wrought), and on anticipated service conditions.

Solution heat treatment improves strength and results in maximum toughness and shock resistance. Artificial aging (precipitation heat treatment) after solution treatment gives maximum hardness and yield strength, but with some sacrifice of toughness. As applied to castings, artificial aging without prior solution treatment or annealing is a stress-relieving treatment that also somewhat increases tensile properties. Annealing of products lowers tensile properties considerably and increases ductility, thereby facilitating some types of fabrication. Modifications of these basic treatments have been developed for specific alloys, to obtain the most desirable combinations of properties. For example, increasing the aging time for some magnesium alloy castings considerably increases yield strength (although with some sacrifice of ductility). Also, combinations of solution treating, strain hardening, and artificial aging are applied to alloy HM21A sheet to improve mechanical properties over those attainable by solution treating and artificial aging alone.

For certain magnesium alloys, development of properties depends almost entirely on heat treatment. In magnesium-zirconium alloys, however, the extremely pronounced grain-refining effect of the zirconium also plays a very important role in improving mechanical properties.

The basic temper designations outlined in Table 1 for magnesium alloys are used throughout this article to indicate the various types of heat treatment. For a detailed explanation of these designations, which are the same as those applied to aluminum alloys, see the article "Alloy and Temper Designation Systems for Aluminum and Aluminum Alloys," in *Properties and Selection: Nonferrous Alloys and Special-Purpose Materials,* Volume 2, *ASM Handbook.*

Table 1 Basic temper designations

Designation	Expanation
F	As-fabricated
O	Annealed, recrystallized (wrought products only)
H	Strain hardened (wrought products only)
H1	Strain hardened only
H2	Strain hardened and partially annealed
H3	Strain hardened and stabilized
W	Solution heat treated; unstable temper
T	Heat treated to produce stable tempers other than F, O, or H

T2	Annealed (cast products only)
T3	Solution heat treated and cold worked
T4	Solution heat treated
T5	Artificially aged only
T6	Solution heat treated and artificially aged
T7	Solution heat treated and stabilized
T8	Solution heat treated, cold worked, and artificially aged
T9	Solution heat treated, artificially aged, and cold worked
T10	Artificially aged and cold worked

Note: For a more complete explanation of the designations outlined here, see Volume 2 of this *ASM Handbook* series.

The mechanical properties of most magnesium casting alloys can be improved by heat treatment. Casting alloys can be grouped into seven general classes of commercial importance on the basis of composition:

- Magnesium-aluminum-manganese (example: AM100A)
- Magnesium-aluminum-zinc (examples: AZ63A, AZ81A, AZ91C, AZ92A)
- Magnesium-zinc-zirconium (examples: ZK51A, ZK61A)
- Magnesium-rare earth metal-zinc-zirconium (examples: EZ33A, ZE41A)
- Magnesium-rare earth metal-silver-zirconium, with or without thorium (examples: QE22A, QH21A)
- Magnesium-thorium-zirconium, with or without zinc (examples: HK31A, ZH62A, HZ32A)
- Magnesium-zinc-copper(example: ZC63A)

In most wrought alloys, maximum mechanical properties are developed through strain hardening, and these alloys generally are either used without subsequent heat treatment or merely aged to a T5 temper. Occasionally, however, solution treatment, or a combination of solution treatment with strain hardening and artificial aging, will substantially improve mechanical properties. Wrought alloys that can be strengthened by heat treatment are grouped into five general classes according to composition:

- Magnesium-aluminum-zinc (example: AZ80A)
- Magnesium-thorium-zirconium (example: HK31A)
- Magnesium-thorium-manganese (examples: HM21A, HM31A)
- Magnesium-zinc-zirconium (example: ZK60A)
- Magnesium-zinc-copper (example: ZC71A)

Types of Heat Treatment

The heat treatments commonly used for various magnesium alloys, both cast and wrought, are indicated by temper designations in Table 2.

Table 2 Heat treatments commonly applied to magnesium alloys

Alloy	Heat treatment[(a)]
Casting alloys	
AM100A	T4, T5, T6, T61[(b)]
AZ63A	T4, T5, T6
AZ81A	T4
AZ91C	T4, T6
AZ92A	T4, T6
EZ33A	T5
EQ21A	T6
HK31A	T6
HZ32A	T5
QE22A	T6
QH21A	T6
WE43A	T6
WE54A	T6
ZC63A	T6
ZE41A	T5
ZE63A	T6[(c)]
ZH62A	T5

ZK51A	T5
ZK61A	T4, T6
Wrought alloys	
AZ80A	T5
HM21A	T5, T8, T81[(d)]
HM31A	T5
ZC71A	F, T5, T6
ZK60A	T5

(a) Indicated by temper designations (see Table 1).

(b) Same as T6 except aged for longer time to increase yield strength.

(c) Thermal treatment must include hybriding.

(d) Mill modification of T8 to improve mechanical properties

Annealing. Wrought magnesium alloys in various conditions of strain hardening or temper can be annealed by being heated at 290 to 455 °C (550 to 850 °F), depending on alloy, for one or more hours (Table 3). This procedure usually will provide a product with the maximum anneal that is practical. Because most forming operations on magnesium are done at elevated temperature, the need for fully annealed wrought material is less than with many other metals.

Table 3 Annealing temperatures for wrought magnesium alloys

Alloy	Original temper	Annealing temperature[(a)]	
		°C	°F
AZ31B	F, H10, H11, H23, H24, H26	345	650
AZ31C	F	345	650
AZ61A	F	345	650

AZ80A	F, T5, T6	385	725
HK31A	H24	400	750
HM21A	T5, T8, T81	455	850
HM31A	T5	455	850
ZK60A	F, T5, T6	290	550

(a) Time at temperature, 1 h or more

Stress Relieving of Wrought Alloys. Stress relieving is used to remove or reduce residual stresses induced in wrought magnesium products by cold and hot working, shaping and forming, straightening, and welding.

Table 4 gives the recommended stress-relieving times and temperatures for wrought magnesium alloys to obtain assemblies with maximum freedom from stress. When extrusions are welded to hard-rolled sheet, the lower stress-relieving temperature and the longer time should be used to minimize distortion; for example, use 150 °C (300 °F) for 60 min rather than 260 °C (500 °F) for 15 min.

Table 4 Recommended stress-relieving treatments for wrought magnesium alloys

Alloy	Sheet						Extrusions and forgings		
	Annealed			Hard rolled					
	Temperature		Time, min	Temperature		Time, min	Temperature		Time, min
	°C	°F		°C	°F		°C	°F

ZK60A-T5	. . .	. . .	. . .	. . .	. . .	. . .	150	300	60

Note: Stress relieving after welding, to prevent stress-corrosion cracking, is necessary only for alloys that contain more than 1.5% aluminum.

Stress Relieving of Castings. The precision machining of castings to close dimensional limits, the necessity of avoiding warpage and distortion, and the desirability of preventing stress-corrosion cracking in welded magnesium-aluminum casting alloys make it mandatory that cast components be substantially free from residual stresses. Although magnesium castings do not normally contain high residual stresses, the low modulus of elasticity of magnesium alloys means that comparatively low stresses can produce appreciable elastic strains.

Residual stresses may arise from contraction due to mold restraint during solidification, from nonuniform cooling after heat treatment, or from quenching. Machining operations also can result in residual stress and require intermediate stress relieving prior to final machining.

Weld repairs may introduce severe stresses and should be followed by some type of heat treatment to prevent subsequent movement and cracking, as discussed in the section of this article concerning heat treatment of repair-welded castings.

The following heat treatments for castings will provide stress relief without significantly affecting mechanical properties:

Alloy	**Temper**	**Heat treatment**
Mg-Al-Mn	All	1 h at 260 °C (500 °F)
Mg-Al-Zn	All	1 h at 260 °C (500 °F)
ZK61A	T5	2 h at 330 °C (625 °F) and then 48 h at 130 °C (265 °F)

ZE41A	All	2 h at 330 °C (625 °F)

Solution Treating and Aging. Schedules for solution treating and aging of magnesium alloys are summarized in Table 5. In solution treating of magnesium-aluminum-zinc alloys, parts should be loaded into the furnace at approximately 260 °C (500 °F) and then raised to the appropriate solution-treating temperature slowly, to avoid fusion of eutectic compounds and resultant formation of voids. The time required to bring the load from 260 °C (500 °F) to the solution-treating temperature is determined by the size of the load and by the composition, size, weight, and section thickness of the parts, but 2 h is a typical time. All other heat-treatable magnesium alloys can be loaded into the furnace at the solution-treating temperature. For alloy HK31A, it is important to bring the load to temperature as rapidly as possible to avoid grain coarsening.

Table 5 Recommended solution-treating and aging schedules for magnesium alloy castings and wrought alloy ZC71A

For castings up to 50 mm (2 in.) in section thickness; heavier sections may require longer times at temperature.

Alloy	Final temper	Aging[a]			Solution treating[c]					Aging after solution treating

(a) Aging to the T5 temper is done from the as-fabricated (f) condition.

(b) Except where quoted differently.

(c) After solution treatment and before subsequent aging, castings are cooled to room temperature by fast fan cooling, except where otherwise indicated. Use carbon dioxide, sulfur dioxide, or 0.5 to 1.5% sulfur hexafluoride in carbon dioxide as a protective atmosphere above 400 °C (750 °F).

(d) For solution treating, Mg-Al-Zn alloys are loaded into the furnace at 260 °C (500 °F) and brought to temperature over a 2-h period at a uniform rate of temperature increase.

(e) Alternative treatment, to prevent germination (excessive grain growth): 6 h at 413 ± 6 °C (775 ± 10 °F), 2 h at 352 ± 6 °C (665 ± 10 °F), 10 h at 413 ± 6 °C (775 ± 10 °F).

(f) Alternative treatment: 5 h at 232 ± 6 °C (450 ± 10 °F).

(g) Alternative treatment: 4 h at 216 ± 6 °C (420 ± 10 °F).

(h) Alternative treatment: 5 to 6 h at 216 ± 6 °C (420 ± 10 °F).

(i) Alternative treatment, to prevent germination (excessive grain growth): 6 h at 407 ± 6 °C (765 ± 10 °F), 2 h at 352 ± 6 °C (665 ± 10 °F), 10 h at 407 ± 6 °C (765 ± 10 °F).

(j) Quench from solution-treating temperature either in water at 65 °C (150 ° F) or in other suitable medium.

(k) Alloy HK31A castings must be loaded into the furnace already at temperature and brought back to temperature as quickly as possible.

(l) This treatment is adequate for development of satisfactory properties; it may be followed by 16 h at 177 ± 6 °C (350 ± 10 °F) to provide very slight improvements in mechanical properties.

(m) Alloy ZE63A must be solution treated in a special hydrogen atmosphere because its mechanical properties are developed through hydriding of

some of its alloying elements. Hydriding time depends on section thickness; as a guide, 6.4 mm ($\frac{1}{4}$ in.) sections require approximately 10 h, and 19 mm ($\frac{3}{4}$ in.) sections require about 72 h. Following solution treatment, ZE63A should be quenched in oil, water spray, or air blast.

(n) Alternative treatment: 8 h at 218 ± 6 °C (425 ± 10 °F).

(o) Alternative treatment: 10 h at 482 ± 6 °C (900 ± 10 °F)

During aging, magnesium alloy parts should be loaded into the furnace at the treatment temperature, held for the appropriate period, and then cooled in still air. As indicated in Table 5, there is a choice of artificial aging treatments for some alloys; results are closely similar for the alternative treatments given.

Reheat Treating. Under normal circumstances, when mechanical properties are within expected ranges and the prescribed heat treatment has been carried out, reheat treating is seldom necessary. However, if the microstructures of heat-treated castings indicate too high a compound rating, or if the castings have been aged excessively by slow cooling after solution treating, reheat treating is called for. Most magnesium alloys can be reheat treated with little danger of germination (excessive grain growth). When reheat treating of alloy HK31A is necessary, however, the castings should be checked carefully for evidence of germination. To prevent germination in Mg-Al-Zn alloys, solution reheat-treating time should be limited to 30 min (assuming proper solution treatment of thick sections during prior heat treatment).

Effects of Major Variables

Casting size and section thickness, relation of casting size to volume capacity of the furnace, and arrangement of castings in the furnace are mechanical considerations that can affect heat-treating schedules for all metals.

Section Size and Heating Time. There is no general rule for estimating time of heating per unit of thickness for magnesium alloys. However, because of the high thermal conductivity of these alloys, combined with their low specific heat per unit volume, parts reach soaking temperature quite rapidly. The usual procedure is to load the furnace and to begin the soaking period when the loaded furnace reaches the desired temperature.

The heat-treating times given in Table 5 have been found to be satisfactory for normal furnace loads and for castings of moderate section thickness. In the heat treating of magnesium alloy castings with thick sections (occasionally as low as 25 mm, or 1 in. but usually over 50 mm, or 2 in.), a good rule is to double the time at the solution-treating temperature. For example, the usual solution treatment for AZ63A castings is 12 h at about 385 °C (725 °F), whereas 25 h at about 385 °C is suggested for castings with section thicknesses greater than 50 mm (2 in.). Similarly, the suggested solution-treating schedule for preventing excessive grain growth in AZ92A castings is 6 h at about 405 °C (765 °F), 2 h at about 350 °C (665 °F), and 10 h at about 405 °C; but for castings with sections more than 50 mm (2 in.) thick, it is recommended that the last soak at 405 °C be extended from 10 to 19 h. The best way to determine whether additional solution-treating time is required is to cut a section through the thickest portion of a scrap casting and examine the center of the section microscopically: if heat treatment is complete, this examination will reveal a low compound rating.

Heat-Treating Time and Temperature. As demonstrated by the data in Fig. 1, 2, 3, and 4, the mechanical properties of magnesium alloys can be varied within wide limits by varying the heat-treating times and temperatures recommended in Table 5. Although the highest mechanical properties in test bars of QE22A-T6 (Fig. 1) were obtained by solution treating for 4 h at 540 °C (1000 °F), less distortion due to sagging is experienced in production castings solution treated for 8 h at 525 °C (980 °F). The risk of incipient melting can also occur at the higher temperature.

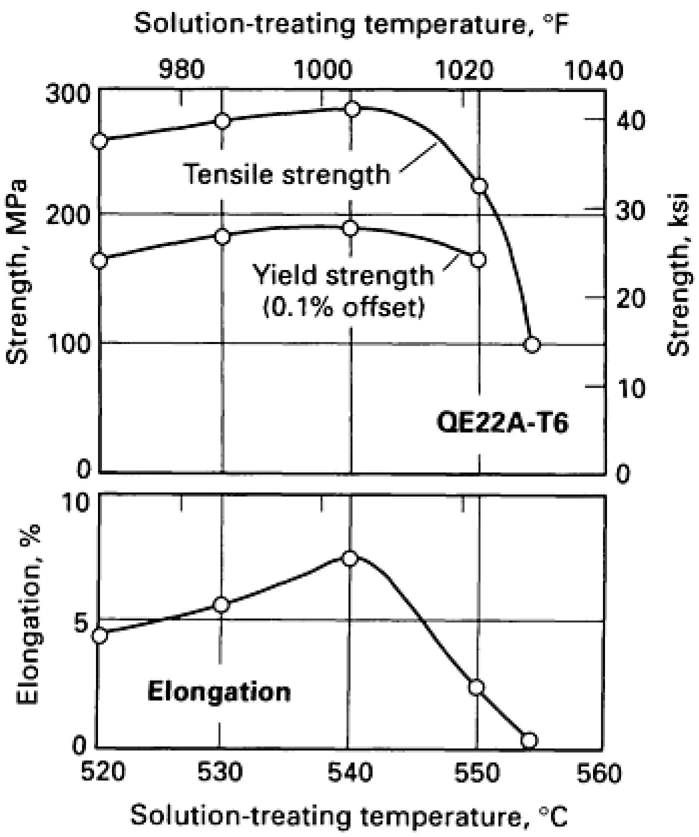

Fig. 1 Tensile properties of alloy QE22A-T6 as functions of solution-treating temperature. Data were obtained from test bars of casting alloy QE22A-T6 machined from 25 mm (1 in.) diam cast specimens. The bars were held at temperature for 4 h.

Protective Atmospheres. Although magnesium alloys can be heat treated in air, protective atmospheres are almost always used for solution treating. Government specification MIL-M-6857, for heat treating of magnesium castings, requires a protective atmosphere for solution treating above 400 °C (750 °F). Protective atmospheres serve the dual purpose of preventing surface oxidation (which, if severe, can decrease strength) and of preventing active burning should the furnace exceed proper temperature.

The three gases normally used are sulfur hexafluoride, sulfur dioxide, and carbon dioxide. Inert gases also may be used; however, in most instances, these gases are not practical because of higher cost. A concentration of 0.5 to 1.5% sulfur hexafluoride in carbon dioxide will prevent active burning above 600 °C (1110 °F). Sulfur dioxide is available bottled, whereas carbon dioxide may be obtained either bottled or as the product of recirculated combustion gases from a gas-fired furnace. A concentration of 0.7% (0.5% min) sulfur dioxide will prevent active burning to a temperature of 565 °C (1050 °F), provided that melting of the alloy has not occurred. Carbon dioxide in a concentration of 3% will prevent active burning to 510 °C (950 °F), and a carbon dioxide concentration of 5% will provide protection to about 540 °C (1000 °F).

Sulfur hexafluoride is more expensive than either sulfur dioxide or carbon dioxide but has the advantage of being nontoxic and noncorrosive. Sulfur dioxide is also more expensive on a volume basis than carbon dioxide, but the volume

of sulfur dioxide required for a protective atmosphere is only $\frac{1}{6}$ the volume of carbon dioxide required. Thus, the cost of producing a protective atmosphere with bottled gases is less using sulfur dioxide. Where gas-fired furnaces are used and the atmosphere is obtained by recirculating combustion gases, a carbon dioxide atmosphere has the lower cost.

The use of sulfur dioxide requires frequent cleaning of furnace controls and fixtures and replacement of furnace parts because of the formation of corrosive sulfuric acid in the furnace system. When heat treating both magnesium and aluminum alloy castings in the same furnace is desired, a carbon dioxide atmosphere is required because sulfur dioxide is harmful to aluminum. Government regulations regarding the use of sulfur dioxide also suggest the use of carbon dioxide.

Equipment and Processing

In solution treating and artificial aging of magnesium alloys, it is standard practice to use an electrically heated or gas-fired furnace equipped with a high-velocity fan or comparable means for circulating the atmosphere and promoting uniformity of temperature. However, because the atmosphere for solution treating sometimes contains sulfur dioxide, only furnaces that are gastight and that provide an inlet for introducing protective atmosphere are suitable.

The atmosphere is circulated past the heating elements and through the load in the basket. A rapid rate of circulation is necessary for maintaining an even distribution of temperature throughout the load. The minimum rate of circulation varies with furnace design and loading practice; one manufacturer recommends a rate equivalent to about 45 changes of atmosphere per minute.

Furnace Loading. Loading of furnaces used for heat treatment of magnesium parts is an important consideration. Parts must be clean and free from grinding dust, shavings, chips, sawings, and other fines; this is particularly important at the higher temperatures used for solution treatment. A furnace load should be comprised of only one alloy composition because of the variation in nonequilibrium fusion points among various alloys. Furnaces should be loaded in an orderly manner that will not interfere with air circulation and cause uneven heating.

Temperature Control. A high degree of temperature control is required for heat treating of magnesium alloys. As indicated in Table 5, the maximum allowable temperature variation is ±6 °C (±10 °F) for the solution-treating operation.

The safest and most suitable temperature-control system for solution and precipitation treating of magnesium alloys consists of three types of furnace controls. The first control detects the temperature within the heating chamber and controls the source of heat so as to attain and hold a desired predetermined temperature. This control is composed of a temperature-sensing device (usually a thermocouple) and a recording controller.

The second control is a furnace-charge-temperature sensor and is used to determine when the load has reached temperature. It consists of a thermocouple strategically located in the charge and a temperature-indicating device; an indicator-controller may be used to actuate an alarm, signal, or timing device to indicate that the charge has reached temperature. This control is useful for preventing overshooting of the desired maximum temperature because of high heat input or because the load is small in comparison with the size of the furnace.

The third control is a safety device and is used to prevent serious overheating of the load or a possible magnesium fire. It consists of a thermocouple, usually located in the roof of the furnace, and an indicating controller that will turn off the source of heat to the furnace. This controller should require resetting before the furnace will heat again.

Quenching Media. Magnesium alloy products normally are quenched in air following solution treatment. Still air usually is sufficient; forced-air cooling is recommended for dense loads or for parts that have very thick sections. The only common exceptions to air quenching are alloys QE22A and QH21A, for which water quenching at 60 to 95 °C (140 to 200 °F) is used to develop the best mechanical properties. Glycol or oil quenchants will produce similar properties with reduced distortion. For QE22A products subject to distortion as a result of the severity of water quenching, air cooling may be used provided that the cooling rate exceeds 3 °C/s (5 °F/s). The effects of quenching in still air, in forced air, and in water at 65 °C (150 °F) on the tensile properties of separately cast test bars of QE22A-T6 are indicated by the data in Table 6.

Table 6 Effect of quenching medium on average tensile properties of QE22A-T6

Quenching medium	Tensile strength		Yield strength[(a)]		Elongation[(b)], %
	MPa	ksi	MPa	ksi	
Still air[(c)]	232	33.6	158	22.9	3.8
Air blast[(c)]	250	36.2	182	26.4	3.5
Water at 65 °C (150 °F)[(c)]	270	39.2	190	27.5	3.0
30% glycol at room temperature[(d)]	269	39.0	190	27.5	3.0

(a) At 0.2% offset.

(b) In 50 mm or 2 in.

(c) Properties determined on bars machined from 25 mm (1 in.) diam separately cast specimens.

(d) Properties determined on bars machined from castings

Control of Distortion. The strength of cast magnesium alloys decreases at elevated temperature to such an extent that it is often necessary during solution treating to prevent intricate castings from sagging from their own weight and to keep flat castings from warping as a result of the relief of casting stresses. To accomplish these ends, tie bars are made an integral part of the casting, simple fixturing is used, or complicated cast or machined fixtures are produced. The method used depends on the complexity and quantity of castings to be made, and on the degree of dimensional control required. Whatever the method, it should not interfere unnecessarily with the free circulation of heat about the castings. Although fixturing decreases warpage of castings, some castings still require straightening after solution treating. Straightening is most readily done after solution treating, prior to aging.

Prevention of Heat-Treating Problems

Six common problems that may be encountered in heat treating magnesium alloys are oxidation, fusion voids, warpage, grain coarsening, germination, and inconsistent properties. Causes and prevention are discussed in Table 7.

Table 7 Causes and prevention of problems commonly encountered in heat treatment of magnesium alloys

Oxidation
Cause: Heat treating without use of protective or inert atmosphere; can lead to local weakening of the metal part, and even to burning of the metal in the furnace.
Prevention: Heat treat in a controlled atmosphere containing about 0.5 to 1.5% SO_2 or 3 to 5% CO_2, or 0.5 to 1.5% SF_6 in CO_2, or (less practical because more costly) in an inert-gas atmosphere. Ensure that furnace is clean and completely dry.

Fusion voids
Cause: Use of improper rate of heating from 260 to 370 °C (500 to 700 °F) for Mg-AI-Zn alloys, or exceeding recommended temperature in solution heat treating of these alloys or of the alloys that contain zinc, thorium, and rare earth metals as major alloying elements. Fusion voids are not normally observed when the solidus temperature of the Mg Zr alloys is exceeded. In this instance that grain-boundary phase will run along the grain-boundary forming long, narrow regions. This is normally accompanied by grain coarsening.
Prevention: Charge furnace with Mg-Al-Zn alloys at 260 °C (500 °F) and then heat gradually to solution-treating temperature over a period of 2 h. Control solution temperature so as not to exceed designated temperature by more than 6 °C (10 °F).
Warpage
Cause: Lack of support of castings during heat treatment; uneven distribution of heat.
Prevention: Support long spans of thin cross section; use jigs for intricate shapes. Distribute load in furnace to obtain good circulation of atmosphere.
Grain coarsening
Cause: Occurs in HK31A as a result of delay in attaining solution temperature or of holding at solution temperature for an excessive period.
Prevention: Prior to solution treating of HK31A, furnace should be at temperature; castings should be loaded quickly, and the loaded furnace should be closed and brought to temperature as rapidly as possible. Time at temperature should be controlled.
Germination
Cause: Grain growth, which occurs in AM 100A, AZ81A, AZ91C, and AZ92A toward the end of the solution-treating cycle.
Prevention: Use antigermination heat-treating schedules (presented as alternative treatments in footnotes [e] and [j] in Table 5).
Inconsistent properties
Cause: Insufficient or excessive furnace temperature, inadequate circulation of heat in the furnace, faulty temperature control, very slow cooling from the solution-treating temperature, or inadequate solution-treating time for heavy sections.
Prevention: Check temperature at various positions in furnace with standardized thermocouple. Distribute castings in furnace to provide adequate circulation of heat. Check temperature controls often, and ensure that controls are located so as to provide uniformity of temperature. Increase solution-treating time to allow complete homogenization.

Dimensional Stability. In normal service up to approximately 95 °C (200 °F), all magnesium casting alloys exhibit good dimensional stability and can be considered free from additional dimensional changes.

Some cast magnesium-aluminum-manganese and magnesium-aluminum-zinc alloys in certain tempers exhibit slight permanent growth after relatively long exposure to temperatures exceeding 95 °C (Fig. 5 and 6). This growth, although slight, can give rise to problems as in the following example.

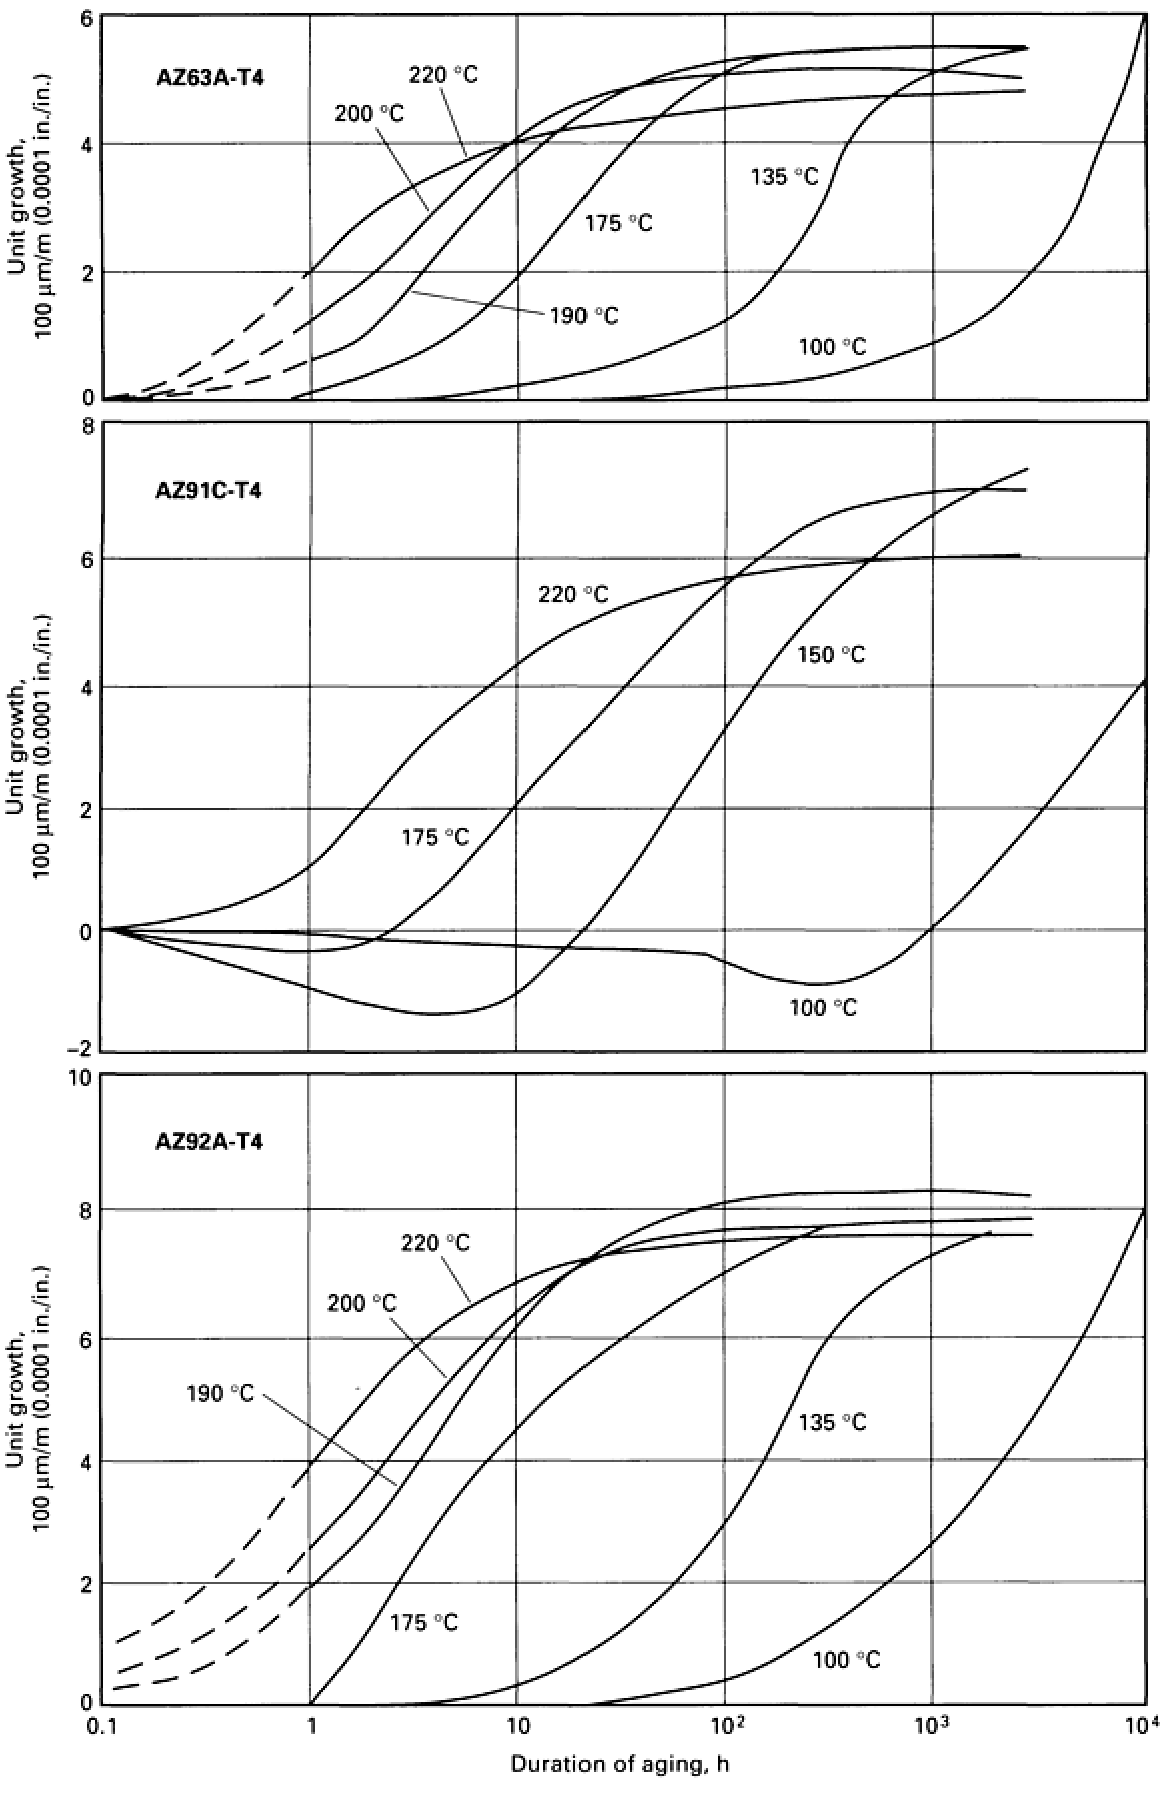

Fig. 5 Variation of growth with aging time and temperature for solution-treated AZ63A, AZ92A, and AZ91C

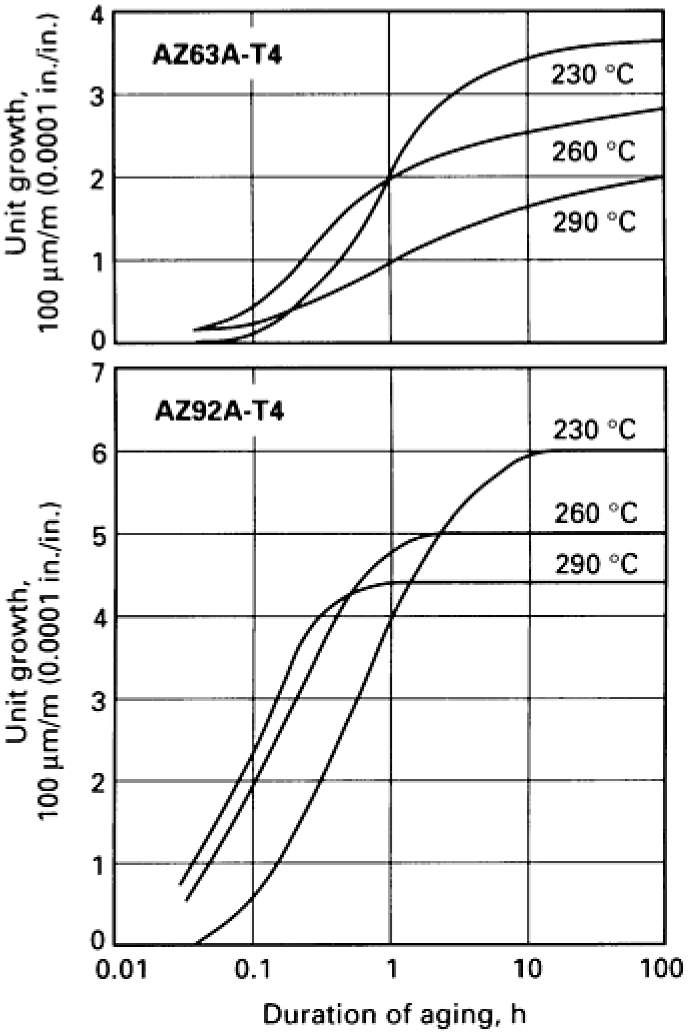

Fig. 6 Variation of growth with aging time and temperature for solution-treated AZ63A and AZ92A

Example: Dimensional Change of Engine Cover Plate.

An aircraft-engine cover plate, sand cast of alloy AZ63A, was used in the as-cast condition (F temper), and the operating temperature of the engine was high enough to cause growth. As a result of this growth, it was necessary to pry off the cover plate when the engine was taken down for overhauling, and the plate could not be replaced because the holes did not line up properly with mating studs. This problem could have been eliminated by proper choice of temper (T5 or T6) prior to placing the cover in service.

In contrast to the growth characteristics of the magnesium-aluminum-zinc alloys are those of the magnesium alloys containing thorium, rare earth metals, and zirconium as major alloying elements. These alloys normally are used in the T5 or T6 temper, and they shrink, rather than grow, on exposure to elevated temperature (Table 8).

Table 8 Contraction of magnesium casting alloys at elevated temperatures

Alloy	Temperature		Unit contraction, 100 μin/m (0.0001 in./in.), after exposure time, h, of			
	°C	°F	10	100	1000	5000

Heat Treatment of Weld-Repaired Castings

Magnesium sand castings that have been reclaimed or repaired by welding may be subsequently heat treated to relieve residual stresses. Heat treatment also may be necessary for restoring the mechanical properties of the casting when these have been impaired or modified by preheating prior to welding, or for heat treating the weld zone as such.

Table 9 shows the heat-treating schedules recommended for magnesium castings after welding. The heat-treating procedures shown are based on both the temper of the casting before the welding operation and the temper desired after welding. These postwelding heat treatments are normally all that is required for adequate stress relief of castings and for optimum mechanical properties in weld areas. The solution treatments here require the use of a protective atmosphere to prevent oxidation or burning. Only the minimum time for complete solution ($\frac{1}{2}$ h) is used for the welded casting alloys AZ81A, AZ91C, and AZ92A if the castings were in the T4 or the T6 condition prior to welding.

Table 9 Postweld heat treatments for magnesium alloy castings

Alloy	Welding rod	Temper before welding	Desired temper after welding	Postweld heat treatment
AZ63A	AZ63A or AZ92A[(a)]	F	T4	12 h at 385 ± 6 °C (725 ± 10 °F)[(b)]

	AZ92A[a]	F	T6	12 h at 385 ± 6 °C (725 ± 10 °F)[b], plus 5 h at 220 °C (425 °F)
		T4	T4	$\frac{1}{2}$ h at 385 ± 6 °C (725 ± 10 °F)
		T4 or T6	T6	$\frac{1}{2}$ h at 385 ± 6 °C (725 ± 10 °F), plus 5 h at 220 °C (425 °F)
AZ81A	AZ92A or AZ101	T4	T4	$\frac{1}{2}$ h at 413 ± 6 °C (775 ± 10 °F)[c]
AZ91C	AZ92A or AZ101	T4	T4	$\frac{1}{2}$ h at 413 ± 6 °C (775 ± 10 °F)[c]
		T4 or T6	T6	$\frac{1}{2}$ h at 413 ± 6 °C (775 ± 10 °F)[c], plus 4 h at 215 °C (420 °F) or 16 h at 170 °C (335 °F)
AZ92A	AZ92A	T4	T4	$\frac{1}{2}$ h at 407 ± 6 °C (765 ± 10 °F)[c]
		T4 or T6	T6	$\frac{1}{2}$ h at 407 ± 6 °C (765 ± 10 °F)[c], plus 4 h at 260 °C (500 °F) or 5 h at 220 °C (425 °F)
EQ21A	EQ21A	T4 or T6	T6	1 h at 505 ± 6 °C (940 ± 10 °F), quench, 16 h at 205 °C (400 °F)
EZ33A	EZ33A	F or T5	T5	2 h at 345 °C (650 °F)[d], and/or 5 h at 215 °C (420 °F), or 24 h at 220 °C (425 °F)
HK31A	HK31A[g]	T4 or T6	T6	16 h at 205 °C (400 °F)[e]
HZ32A	HZ32A[g]	F or T5	T5	16 h at 315 °C (600 °F)
QE22A	QE22A	T4 or T6	T6	1 h at 510 ± 6 °C (950 ± 10 °F), quench, 16 h at 205 °C (400 °F)
QH21A	QH21A	T4 or T6	T6	1 h at 510 ± 6 °C (950 ± 10 °F), quench, 16 h at 205 °C (400 °F)
WE43A	WE43A	T4 or T6	T6	1 h at 510 ± 6 °C (950 ± 10 °F), quench, 16 h at 205 °C (400 °F)

WE54A	WE54A	T4 or T6	T6	1 h at 510 ± 6 °C (950 ± 10 °F), quench, 16 h at 205 °C (400 °F)
ZC63A	ZC63A	T4 or T6	T6	1 h at 425 ± 6 °C (797 ± 10 °F), quench, 16 h at 205 °C (400 °F)
ZE41A	ZE41A[(g)]	F or T5	T5	2 h at 330 °C (625 °F)[(f)]
ZH62A	ZH62A[(g)]	F or T5	T5	12 h at 250 °C (480 °F)[(f)]
ZK51A	ZK51A[(g)]	F or T5	T5	2 h at 330 °C (625 °F), plus 16 h at 175 °C (350 °F)

(a) AZ63A rod must be used for welding AZ63A in the F temper because 12 h at 385 °C (725 °F) causes germination in welds made with AZ92A rod; AZ92A rod normally is used for welding AZ63A in the T4 or T6 condition unless AZ63A rod is required by specifications.

(b) Preheat to 260 °C (500 °F); heat to specified temperature at no more than 83 °C/h (150 °F/h).

(c) Use carbon dioxide or sulfur dioxide atmosphere.

(d) Heating for 2 h at 345 °C (650 °F) results in slight loss of creep strength.

(e) Alternative treatment: 1 h at 315 °C (600 °F), plus 16 h at 205 °C (400 °F).

(f) Alternative treatment: 2 h at 330 °C (625 °F), plus 16 h at 175 °C (350 °F).

(g) Or EZ33A

Welded Mg-Al-Zn alloy castings that do not require solution treatment after welding should be stress relieved 1 h at 260 °C (500 °F), to eliminate the possibility of stress-corrosion cracking.

Evaluation of Heat-Treated Parts

The effectiveness of heat-treating procedures can be determined by hardness and tensile tests and by microscopic examination.

Indentation hardness tests are rapid and usually can be performed on the parts heat treated, without the necessity for a special test specimen. Brinell and Rockwell E hardness tests are normally used, but the Rockwell 15T superficial test may be required for thin sections. Soft material with large grains should be tested by the Brinell method for best results. The strength of magnesium alloys usually increases as hardness increases, but a graph of strength values determined from hardness plotted against actual strength values from the same specimens shows so much scatter that hardness cannot be used as an index for strength. Furthermore, hardness cannot indicate how an alloy will machine, or how easily it can be fabricated by other methods; it is primarily a measure of the temper of the material, and normally it suffices for this purpose.

Tensile tests more accurately indicate the temper of magnesium alloys. For casting alloys, test specimens can be separately cast unmachined, although specimens machined from castings are more representative of actual casting

properties. Test bars must be machined from extrusions, forgings, and sheet. Test bars from extrusions and forgings are machined round for convenience. Standard ASTM specimens and procedures are usually employed to help ensure uniform results and avoid errors from variable testing speed, presence of scratches, and other causes.

Microscopic examination of heat-treated magnesium alloys can be used to evaluate the alloy for the following conditions:

- Massive compound in cast alloys
- Percentage of pearlitic type of precipitate in cast alloys
- Porosity and "burning" voids in improperly solution heat-treated cast alloys
- Grain size in cast and wrought alloys
- Massive compound in extruded, forged, or rolled alloys

These conditions can be easily detected by comparing polished specimens with standard micrographs.

Determination of Temper. For alloys AZ91C and AZ92A, the following solution can be applied to heat-treated parts to identify the T6 conditions: 60 parts ethylene glycol; 20 parts glacial acetic acid; 19 parts distilled water; 1 part nitric acid, 42° Be. For ZE41A, the following solution can be applied to heat-treated parts to identify the T5 condition: 5 parts glacial acetic acid; 95 parts distilled water. For either of these tests, the test surface should be prepared by sanding first with 180-grit paper and then with 220- to 400-grit paper to produce a smooth area about 25 mm (2 in.) square. After the test section has been wiped clean, one drop of the solution is applied with an eyedropper. After 30 s, the test section is rinsed with water and blotted dry with a piece of soft cloth.

For AZ91C and AZ92A, the surface of a part in a T6 condition will appear darker where etched. For ZE41A, the surface will appear lighter where etched if the part is in the T5 condition. This alloy will show a bluish tint in the as-cast condition, whereas alloy ZE41A in the T5 temper--either 2 h at 330 °C (625 °F) or 2 h at 330 °C plus 16 h at 175 °C (350 °F)--tends to show a brown-to-beige tint.

The inspected area should be wiped clean, and a fresh type I chrome pickle should be applied to prevent corrosion.

Prevention and Control of Magnesium Fires

Improper heat treating of magnesium alloy castings not only will result in damaged castings but also may cause fire. Only clean, dry castings should be introduced into the furnace. Castings contaminated with filings, chips, oil, or other foreign matter should first be cleaned. The furnace itself should be protected from these same contaminants and should be completely dry. The charge should consist of castings of only one alloy, and the recommended heat-treating cycle for that alloy should be closely followed.

Occasionally, because of equipment malfunction, carelessness, or operator error, fires do occur. They are usually detectable either by an increase in furnace temperature without an increase in input of heat or by seepage of light-colored smoke from the furnace.

Caution: Under no circumstance should water be used to extinguish a magnesium fire.

All power, fuel, and protective-atmosphere lines should be shut off immediately. This in itself may extinguish small fires, which will die from lack of oxygen in a tight furnace. Should the fire continue to burn, several methods of extinguishing it are possible, depending on the nature of the fire. If the fire is small and the burning castings are readily accessible and can be *safely* removed from the furnace, they should be removed to a steel container and covered with commercially available fire-extinguishing powder intended for use with magnesium. If the burning castings are not both safely and readily accessible, a pump can be used to throw a stream of powder onto the burning castings in the furnace.

When the fire is such that neither of the above methods can safely be used for extinguishing it, another method is the use of boron trifluoride (BF_3) or boron trichloride (BCl_3), both of which are available as bottled gases. As with the other methods, all power, fuel, and protective-atmosphere lines should be shut off.

Boron trifluoride gas is introduced into the furnace through a pipe in the furnace door or wall so that a minimum concentration of 0.04% is produced. The gas flow is continued until the fire is extinguished and the temperature of the furnace drops to 370 °C (700 °F). Teflon hose is suitable for transferring the pressurized boron trifluoride gas from bottle to furnace.

Boron trichloride gas also is introduced into the furnace through a pipe in the furnace door or wall, in a concentration of about 0.4%. To ensure a sufficient volume of gas, a bank of infrared lamps or some other suitable device is required for heating the bottled gas. Boron trichloride gas reacts with hot magnesium to form a protective film over the castings. A supply of gas is maintained until the fire is extinguished and the temperature of the furnace drops to 370 °C (700 °F). In a totally enclosed furnace, it is feasible to employ the furnace fan to circulate the boron trifluoride or boron trichloride extinguishing gas around the castings. (Teflon hose can be used for transferring the boron trichloride gas from the bottle to the furnace.)

Boron trichloride predates boron trifluoride as a fire extinguisher for magnesium. Boron trifluoride is preferred because it is effective in lower concentration, it does not require a heat source to ensure an adequate supply of gas, and its reaction products are less hazardous than those of boron trichloride. The fumes of boron trichloride are irritating and are ranked with hydrochloric acid fumes as a health hazard.

If the heat-treating furnace fire includes more than several hundred pounds of magnesium parts, is well advanced prior to discovery, involves a large pool of metal on the floor of the furnace, or is in a furnace with excessive air leaks, these gases cannot be expected to extinguish the fire completely. However, both boron trifluoride and boron trichloride are effective in slowing or suppressing the fire until it can be extinguished with other solid materials.

Dry cast iron chips, graphite powder combined with heavy hydrocarbons, and (occasionally) foundry melting flux have been used for extinguishing large magnesium fires; the effectiveness of these materials is based on smothering the fire from the oxygen of the atmosphere in the furnace.

Besides the normal safety equipment used by personnel in fire fighting, colored glasses should be used when fighting a magnesium fire, for protection of the eyes against the characteristic intense white light.

Heat Treating of Nickel and Nickel Alloys

Donald J. Tillack, James M. Manning, and J.R. Hensley, Inco Alloys International, Inc.

Introduction

NICKEL AND THE NICKEL ALLOYS are, in some ways, easier to heat treat than many of the iron-base alloys that depend on carbon-related microstructural changes to achieve desired properties. Nickel is an austenite former, and in the nickel and high-nickel family of alloys, no allotropic phase transformations occur--the alloys are austenitic from the melting temperature down to absolute zero. While some precipitates may form such as carbides and the γ' hardening phase, these do not change the basic austenitic-type structure of the matrix. (See the article "Heat Treating of Superalloys" in this Volume for discussions on the formation of carbides and γ' precipitates.)

Because nickel is found in nature as nickel sulfide and nickel oxide ores, it has a natural tendency to combine with sulfur and/or oxygen. One of the most important factors to consider when heat-treating nickel or the nickel alloys is to minimize exposure to sulfur, whether in solid form (such as lubricants, grease, or temperature-indicating sticks) or in gaseous form (such as SO_2 or H_2S). When embrittlement by sulfur occurs, there are no techniques that can be used to reclaim the affected material; the contaminated area must be either removed, such as by grinding, or scrapped.

Because nickel has a very low solubility for carbon in the solid state, it does not readily carburize. For this reason the nickel-chromium alloys, most notably Inconel 600, are used as fixtures in carburizing furnaces. Almost all heat treatment methods used with nickel and the nickel alloys are employed either to soften them, such as annealing, or to increase their strength, such as age hardening.

Types of Heat Treatment

Nickel and the nickel alloys may be subjected to one or more of six principal types of heat treatment, depending on chemical composition, fabrication requirements, and intended service. These methods include:

- *Annealing.* A heat treatment designed to produce a recrystallized grain structure and softening in work-hardened alloys. Annealing usually requires temperatures between 705 and 1205 °C (1300 and 2200 °F), depending on alloy composition and degree of work hardening
- *Solution annealing.* A high-temperature anneal (1150 to 1315 °C, or 2100 to 2400 °F) of certain nickel alloys to put carbides in solid solution and produce a coarse grain size for enhanced stress-rupture properties
- *Stress relieving.* A heat treatment used to remove or reduce stresses in work-hardened non-age-hardenable alloys without producing a recrystallized grain structure. Stress-relieving temperatures for nickel and nickel alloys range from 425 to 870 °C (800 to 1600 °F), depending on alloy composition and degree of work hardening
- *Stress equalizing.* A low-temperature heat treatment used to balance stresses in cold-worked material without an appreciable decrease in the mechanical strength produced by cold working
- *Solution treating.* A high-temperature heat treatment designed to put age-hardening constituents into solid solution. Normally applied to age-hardenable materials before the aging treatment
- *Age hardening* (precipitation hardening). A treatment performed at intermediate temperatures (425 to 870 °C, or 800 to 1600 °F) on certain alloys to develop maximum strength by precipitation of a dispersed phase throughout the matrix

Figure 1 shows the effect on room-temperature mechanical properties of colddrawn Monel 400 rod when the rod is held for 3 h at various temperatures. Heating at 700 °C (1300 °F) or above produces the soft annealed condition; heating in the range of 400 to 595 °C (750 to 1100 °F) results in stress relieving; and heating in the range of 260 to 480 °C (500 to 900 °F) results in stress equalization, which produces an increase in the proportional limit, a slight increase in tensile strength and no significant change in elongation.

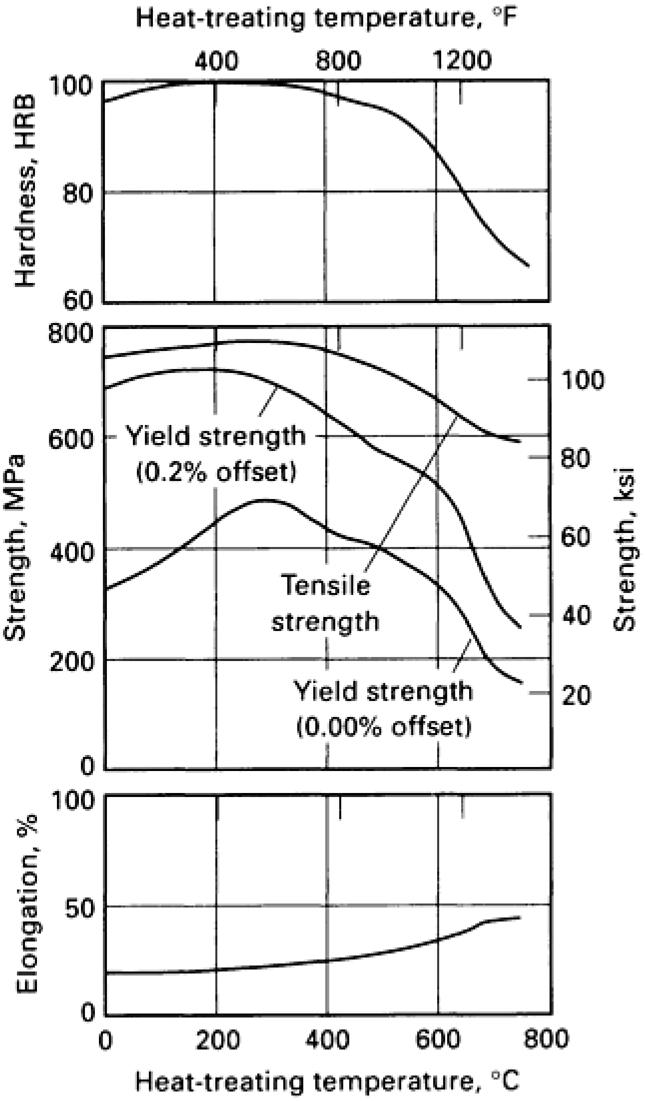

Fig. 1 Effects on room-temperature properties of cold-drawn Monel 400 rod held for 3 h at various temperatures

Annealing

The annealing of nickel and nickel alloys consists of heating the metal at a predetermined temperature for a definite time and then slowly or rapidly cooling it to produce a change in mechanical properties, usually a complete softening, as the result of recrystallization. Nickel and nickel alloys that have been hardened by cold-working operations, such as rolling, deep drawing, spinning, or severe bending, require softening before cold working can be continued. The thermal treatment that does this is known as annealing, or soft annealing.

The differences in chemical composition among nickel and nickel alloys (Table 1) necessitate modifications in annealing temperatures (Table 2) and furnace atmospheres. The precipitation-hardening alloys must be cooled rapidly after annealing if maximum softness is desired. Annealing methods may be divided into three categories: batch, continuous, and specialty. These are described below.

Table 1 Nominal compositions of nickels and nickel alloys

Material	Composition, wt%

	Ni	C	Mn	Fe	Si	Cu	Cr	Ti	Al	Mo	Co	Other

(a) Times given represent actual ranges that thin sheet/strip products and heavy cross sections would receive in continuous furnaces.

(b) AC, air cool: WQ, water quench

Batch annealing is a frequently used method of annealing because of its simplicity. It is the method of choice if the material requires a period of soak at temperature. The furnaces can be open (material exposed to products of combustion or direct radiant heat from electrical elements) or closed (material indirectly heated, that is, a muffle is used). Open annealing is used most often. The material to be annealed is heated at the selected temperature and protected from oxidation, in a fuel-heated furnace by the products of combustion and in an electric furnace by a reducing gas. During preliminary heating of the furnace, the burners may be adjusted for optimum combustion, but, before charging, the air supply should be reduced to provide the excess of reducing gases required. Also the top vents or dampers should be partly or fully closed to provide a positive gas pressure over the hearth, thereby preventing air leakage. Closed-annealing

temperature control is just as critical as in open annealing. What dictates closed as opposed to open annealing is usually the undesirability of oxide on the work. Closed annealing invariably has a protective atmosphere within the enclosure to minimize oxidation during heat treatment. In most instances, the weight of the protective cover exceeds that of the work; consequently, the amount of fuel required, heat times, and cost are greater than in open annealing. Parts are usually carried into the furnace in alloy trays, and a protective atmosphere is introduced. The atmosphere flows continuously during annealing, pressurizing the furnace and preventing the infiltration of outside air. If the protective atmosphere is CO or H_2, the gas should be flared off as it escapes the enclosure.

Continuous Annealing. A continuous-annealing facility is used when large volumes of product are involved and high throughput desired. Continuous furnaces are complex, requiring more frequent inspections and maintenance than a batch-type furnace, and the initial capital outlay is usually higher than for a comparable batch unit. Most continuous furnaces are of the open variety in which the nickel parts are exposed directly to the products of combustion. Temperature control is critical because the annealing period is short (Table 2). Continuous furnaces are not used for extended soaks; the hot-zone dwell time is quite short compared to a batch furnace. Also, temperature uniformity within the hot zone is more difficult to achieve because of the constant introduction of cold metal into the furnace. Closed annealing in a continuous furnace has the same characteristics as batch furnace annealing. The necessity to minimize oxidation is critical; the reducing atmosphere is continually introduced into the furnace, creating a positive furnace pressure. Most heat treatments of this nature take place in an alloy muffle or supertight furnace lined with high-quality alumina brick for better control of atmosphere and quality.

Specialty Annealing. These processes are so specialized and/or difficult that a separate category has been established to fully recognize their uniqueness. Specialty annealing methods include the use of vacuum furnaces, salt baths, and fluidized-bed furnaces. The percentage of nickel alloys heat treated in these types of facilities is small but growing. Brief descriptions are given below.

Vacuum Furnace. This type of furnace is used extensively for small parts. The furnace is usually heated electrically, and the hot zone evacuated to about 5 to 6 μm. A small amount of hydrogen is then added to maintain the low oxygen pressures needed to prevent oxidation. The hot zone is sometimes back-flushed with an inert or reducing gas for cooling purposes. Material must be very clean prior to annealing.

Salt Bath Furnace. Salt bath annealing is used for special work with small parts. Inorganic salts, such as chlorides and carbonates of sodium, potassium, and barium, which are relatively stable at temperatures considerably above their respective melting points, are fused in large metallic or refractory containers at temperatures up to about 700 °C (1300 °F); at higher temperatures, heat-resisting iron-nickel-chromium alloy pots or refractory containers should be used. Excessive fuming of the bath is an indication that its maximum usable temperature has been exceeded.

Particular care must be exercised to remove all traces of sulfur from the fused salts in order to prevent embrittlement of the work. This may be accomplished in 2 to 3 h by adding to the fused chlorides and carbonates a small amount ($\geq$0.5 kg, or $\geq$1 lb) of a mixture consisting (by volume) of three parts powdered borax and one part powdered charcoal. If testpieces of nickel strip or wire do not embrittle after 3 or 4 h in the purified salt bath, the desulfurizing treatment has been sufficient.

The material to be annealed is placed in the molten salts and absorbs heat rapidly. After being annealed, the work metal is quenched in water to free it from particles of the salt mixture. The annealed material will not be bright and may be flash pickled to achieve a bright surface.

Fluidized-bed furnace is a relatively new development. It has the excellent temperature uniformity and rapid heat-up features of the salt bath furnace, without the safety hazards associated with molten salt. Typically, a bed of 80 mesh alumina powder is fluidized by flowing a gas up through the material at 140 MPa (20 psig) pressure. The fluidizing gas is usually either air or metallurgical-grade nitrogen.

Dead-Soft Annealing. When the nickel alloys are annealed at higher temperatures and for longer periods, a condition commonly described as dead-soft is obtained, and the hardness numbers that result are 10 to 20% lower than those of the so-called soft condition. Because this treatment is accompanied by an increase in the grain size of the metal, it should be used only for those few applications in which grain size is of little importance.

Torch Annealing. Some large equipment is hardened locally by fabricating operations. If the available annealing furnace is too small to hold the workpiece, the hardened sections can be annealed with the flames of oil or acetylene

torches adjusted so that they are highly reducing. The work should first be warmed gently with sweeping motions of the torch and should not be brought to the annealing temperature until sufficient preheating has been done to prevent cracking as a result of the sudden release of stress. (It should be noted that torch annealing is a poor method for general use because it provides irregular and insufficient annealing and produces heavily oxidized surfaces.)

Process Control Factors in Annealing

Among the more important process control factors in annealing nickel and nickel alloys are the selection of suitably sulfur-free fuels for heating, control of furnace temperature, effects of prior cold working and of cooling rates, control of grain size, control of protective atmospheres, and protection from contamination by foreign material.

Fuels for Heating. Nickel and nickel alloys are subject to intergranular attack when heated in the presence of sulfur or sulfur compounds. Fuels for heating must be low in sulfur content.

Gas is the best fuel for heating nickel alloys and should be used if available. Good heating is achieved readily with gas because of the ease with which gas can be mixed with air and its supply controlled. Gaseous fuels require little combustion space, and the automatic control of temperature and furnace atmosphere is easily accomplished.

Natural gas, consisting chiefly of methane (CH_4) and smaller amounts of ethane (C_2H_6), propane (C_3H_8), and butane (C_4H_{10}), and essentially free of sulfur compounds, is available in many areas.

Bright Annealing. The temperatures required for the soft annealing of nickel and nickel alloys are sufficiently high to cause slight surface oxidation unless the materials are heated in vacuum or in a furnace provided with a reducing atmosphere. Nickel 200, Monel 400, and similar alloys remain bright and free from discoloration when heated and cooled in a reducing atmosphere. However, nickel alloys containing chromium, titanium, and aluminum form a thin oxide film. Even if oxidation is not important, the furnace atmosphere must be suitably sulfur-free and not strongly oxidizing.

The protective atmosphere most commonly used in heating nickel and nickel alloys is that provided by controlling the ratio between the fuel and air supplied to burners firing directly into the furnace. A desirable reducing condition may be obtained by using a slight excess of fuel so that the products of combustion contain at least 4% carbon monoxide plus 4% hydrogen with no more than 0.05% uncombined oxygen. This is considered an 8% reducing atmosphere and can be obtained by burning an air/gas ratio of 9.25/1 of 1160 kJ (1100 Btu) natural gas.

Another method of maintaining desired conditions of furnace atmosphere is to introduce a prepared atmosphere into the heating and cooling chambers. This can be added to the products of combustion in a directly-fired furnace, although the introduction of prepared atmospheres is more commonly practiced with indirectly heated equipment.

Prepared atmospheres suitable for use with nickel and nickel alloys include dried hydrogen, dried nitrogen, dissociated ammonia, and cracked or partially reacted natural gas. Properties of various protective atmospheres are shown in Table 3. Nickels, modified nickels, and nickel-copper alloys can be bright annealed in all of these atmospheres (except for the first one listed in Table 3, that is, completely burned fuel, lean atmosphere) provided the dew point is 4.4 °C (40 °F) or lower. Inconel 600 and other alloys containing chromium, molybdenum, or both, require completely dissociated ammonia or dried hydrogen for bright annealing. A dew point of -51 °C (-60 °F) or lower is necessary with a positive furnace pressure.

Table 3 Prepared atmospheres suitable for annealing of nickels and nickel alloys

Atmospheres 2 through 7 can be used for bright annealing of nickel, modified nickels, and nickel-copper alloys; atmosphere 4 or atmosphere 7 must be used for bright annealing of nickel alloys that contain chromium, molybdenum, or both.

Atmosphere	Air-to-gas ratio[(a)]	Composition, vol %						Dew point (approximate)	
		H_2	CO	CO_2	CH_4	O_2	N_2	°C	°F
1 Completely burned fuel, lean atmosphere	10:1	0.5	0.5	10.0	0.0	0.0	89.0	Saturated[(b)]	Saturated[(b)]

2 Partially burned fuel, medium-rich atmosphere	6:1	15.0	10.0	5.0	1.0	0.0	69.0	Saturated[(b)]	Saturated[(b)]
3 Reacted fuel, rich atmosphere	3:1	38.0	19.0	1.0	2.0	0.0	40.0	20	70
4 Dissociated ammonia (complete dissociation)	No air	75.0	0.0	0.0	0.0	0.0	25.0	-55 to -75	-70 to -100
5 Dissociated ammonia, partially burned	1.25:1[(c)]	15.0	0.0	0.0	0.0	0.0	85.0	Saturated[(b)]	Saturated[(b)]
6 Dissociated ammonia, completely burned	1.8:1[(c)]	1.0	0.0	0.0	0.0	0.0	99.0	Saturated[(b)]	Saturated[(b)]
7 Electrolytic hydrogen, dried[(d)]	No air	100.0	0.0	0.0	0.0	0.0	0.0	-55 to -75	-70 to -100

(a) Based on use of natural gas containing nearly 100% methane and rated at 37 MJ/m^3 (1000 Btu/ft^3). For high-hydrogen manufactured gas (20 MJ/m^3, or 550 Btu/ft^3), ratios are about 50% of values listed. For manufactured gas with lower hydrogen and high carbon monoxide contents (17 MJ/m^3, or 450 Btu/ft^3), ratios are about 40% of values listed. For propane, ratios are about twice those listed. For butane, multiply listed values by three.

(b) When atmosphere is cooled by tap water heat exchangers, dew point will be about 6 to 8 °C (10 to 15 °F) above the temperature of the tap water. Dew point may be reduced to about 5 °C (40 °F) by refrigeration equipment and to -55 °C (-70 °F) or lower by activated-absorption equipment.

(c) Ratio of air to dissociated ammonia.

(d) Dried to a dew point of -55 to -75 °C (-70 to -100 °F) by alumina plus molecular sieve

The conditions for bright annealing should be maintained during heating, regardless of the method used for cooling. If facilities for cooling under protective atmosphere are not available, nickel and nickel alloys may be quenched in a 2% (by volume) solution of denatured alcohol. This will reduce the oxide flash formed by the oxygen of the air during transfer from the furnace to the quenching tank.

Manufactured gases are produced from coal or oil, both of which may contain substantial amounts of sulfur. These gases should not be used unless the sulfur compounds are effectively removed during gas manufacture. Sulfur occurs in these manufactured gases as hydrogen sulfide (H_2S) and organic sulfides.

Suppliers of manufactured gas try to keep the total sulfur content of their product to a value below the maximum set by state regulatory agencies. Thus, manufactured gas supplied to consumers usually contains less than 6.9 g of total sulfur per 10 m^3 of gas (less than 30 gr per 100 ft^3). This sulfur content may vary considerably from day to day, but, where adequate maintenance of sulfur removal is observed by the gas supplier, total sulfur content will average 2.3 to 3.4 g per 10 m^3 (10 to 15 gr per 100 ft^3) or lower. This sulfur content is acceptable for heating nickel alloys; however, the generally accepted statutory limit (6.9 g per 10 m^3, or 30 gr per 100 ft^3) is marginal.

Two other satisfactory gaseous fuels are butane and propane, which are components of natural gas that liquefy and separate out when the gas if compressed. Both fuels are stored and shipped in tank cars that range in capacity from 30 to 57 m^3 (8000 to 15,000 gal); the fuels may be distributed throughout a plant in pipelines as liquids under their own vapor pressures. Butane can be considered in a sense an oil fuel of high volatility, and proper means must be provided for gasifying it by heating, before it is mixed with air for combustion. Propane is more volatile and does not require the application of heat to convert it from liquid to gas. It is obtainable in cylinders equipped with pressure regulators to control the flow of gas. These cylinders are useful for occasional work in heating small objects.

Control of Furnace Temperature. The importance of the accurate control of annealing temperature cannot be overemphasized. Satisfactory indicating, controlling, recording, and controlling-recording pyrometers are available. Iron-Constantan and Chromel-Alumel thermocouples should be changed every three months (or more often, if required). Noble metal thermocouples such as platinum, are the preferred method of measuring and monitoring temperature because of their inherent ability to resist diseasing at elevated temperatures. Their accuracy and sensitivity are equal to or better than those of the nonplatinum thermocouples. All thermocouples should be checked daily for accuracy.

Effect of Prior Cold Work. The greater the amount of cold work to which the material has been subjected before annealing, the lower the temperature required to produce the same degree of softness without increasing grain size and the shorter the time required at any one temperature.

The amount of any type of previous cold work also has a critical influence on the ductility of nickel and nickel alloys after annealing. If only a small amount of cold work is done (for example, ~10% reduction), full ductility for deep drawing and spinning cannot be restored by annealing because of excessive grain growth due to critical strain, even though the hardness is reduced to that of soft material. A minimum of approximately 20% cold working is required between anneals to ensure maximum ductility and softness following annealing.

Effect of Cooling Rate. Neither slow cooling, whether in or out of the furnace, nor rapid cooling by quenching has any specific effect on the softness of the annealed, solid-solution nickel materials. Therefore, rapid cooling is preferable (except for heavy sections, in which it may set up excessive thermal stresses), both as a time-saver and to minimize the amount of oxidation. Some of the age-hardenable alloys, such as Monel K-500, must be cooled rapidly by quenching from the annealing temperature to ensure the maximum response to subsequent age-hardening treatment.

Control of Grain Size. Coarse-grained material is unsuitable for most cold-working operations. A coarse grain in the high-nickel materials cannot be refined by thermal treatment. It can be removed only by cold working sufficiently to effect recrystallization to a smaller grain size during a subsequent annealing treatment. Maximum workability is obtained with material that has been annealed without allowing appreciable grain growth to occur. The average grain diameter should not exceed 0.064 mm (0.0025 in.) (ASTM No. 5). This gives the best combination of ductility to permit extensive deformation, strength to withstand the action of tools, and surface quality to facilitate polishing.

Effect of Fluctuating Atmospheres. If nickel and nickel alloys are annealed in atmospheres that fluctuate between oxidizing (excess of air) and reducing (excess of carbon monoxide or hydrogen), severe inter-crystalline attack will occur, with resulting embrittlement, even though the atmosphere is sulfur-free. This type of embrittlement can be prevented by maintaining a constant and sufficient excess of reducing atmosphere during heating and cooling. Alloys containing chromium or molybdenum are affected less than are nickel and nickel-copper alloys.

Protection from Contamination by Foreign Material. Many of the new lubricants used for deep drawing and spinning contain sulfur or lead and are removable with alkaline cleaner solutions at 82 °C (180 °F). Unless these elements are removed before annealing, they will cause embrittlement. The chlorohydrocarbons used in the past will no longer be permitted due to safety and ecological considerations. Alternate methods, such as water-soluble lubricants, will be required as more restrictive laws are enacted. Lubricants of any type should be removed entirely from the material before annealing. Paints and other adherent substances that may contain sulfur, as well as lead or similarly harmful ingredients, should be removed by appropriate methods before annealing.

Stress Relieving

In stress relieving, careful regulation of time and temperature is required. These variables are usually determined experimentally for each application; some typical ranges are given in Table 2. Figure 1 shows the effect of stress relief, at temperatures from about 400 to about 600 °C (750 to 1100 °F), on the room-temperature properties of Monel 400.

Stress Equalizing

Stress equalizing is a low-temperature heat treatment (Table 2) that results in what is known as partial recovery. This recovery, which precedes any detectable microscopic structural change, consists of a considerable increase in the proportional limit, slight increases in hardness and tensile strength, no significant change in elongation or reduction of area, a balancing of stresses, and the return of electrical conductivity toward its characteristic value for the alloy in the annealed condition.

The temperature required for stress equalizing depends on the composition of the alloy. Figure 1 shows an optimum temperature range of about 230 to 315 °C (450 to 600 °F) for cold-drawn Monel 400 rod. A temperature range of about 275 °C (525 °F) is recommended for commercial use. Long treatment time at this temperature has no detrimental effect.

Stress equalizing is usually applied to coil springs, wire forms, and flat spring stampings. If coil springs are to be given a cold "set," or cold pressing, after coiling, the stress equalization should be carried out *before* the setting operation, which involves stressing the material beyond the elastic limit. Any cold-working stresses set up by this operation are in a direction such that the stresses will benefit, rather than harm, the material. If stress is equalized *after* cold pressing, part of the beneficial cold-working stress is removed.

Age Hardening

The addition of niobium, aluminum, silicon, titanium, and certain other alloying elements to nickel and nickel alloys, separately or in combinations, produces an appreciable response to age hardening. The effect is dependent on both chemical composition and aging temperature; it is caused by the precipitation of submicroscopic particles throughout the grains, which results in a marked increase in hardness and strength.

Prior Solution Treating. Unlike precipitation-hardening stainless steels and aluminum-base alloys, the nickel alloys normally do not require solution treating in the upper annealing temperature range prior to age hardening. However, solution treating may be used to enhance special properties (Table 4). For example, Inconel X-750 may be solution treated for 2 to 4 h at 1150 °C (2100 °F) and air cooled prior to a double (high and low temperature) aging cycle to develop maximum creep, relaxation, and rupture strength at temperatures above about 600 °C (1100 °F). This combination of heat treatments is considered essential for high-temperature springs and turbine blades made of Inconel X-750.

Table 4 Solution-treating and age-hardening schedules for nickel alloys

Alloy	Solution treating				Age hardening
	Temperature		Time, h	Cooling method[a]	
	°C	°F			
Monel K-500	980	1800	$\frac{1}{2}$-1	WQ	Heat to 595 °C (1100 °F), hold 16 h; furnace cool to 540 °C (1000 °F), hold 6 h; furnace cool to 480 °C (900 °F), hold 8 h; air cool.
Inconel 718 (AMS 5662)	980	1800	1	AC	Heat to 720 °C (1325 °F), hold 8 h; furnace cool to 620 °C (1150 °F), hold until furnace time for entire age-hardening cycle equals 18 h; air cool.
Inconel 718 (AMS 5664)	1065	1950	1	AC	Heat to 760 °C (1400 °F), hold 10 h; furnace cool to 650 °C (1200 °F), hold until furnace time for entire age-hardening cycle equals 20 h; air cool.
Inconel X-750 (AMS 5668)	1150	2100	2-4	AC	Heat to 845 °C (1550 °F), hold 24 h; air cool; reheat to 705 °C (1300 °F), hold 20 h; air cool.
Inconel X-750 (AMS 5671)	980	1800	1	AC	Heat to 730 °C (1350 °F), hold 8 h; furnace cool to 620 °C (1150 °F), hold until furnace time for entire age-hardening cycle equals 18 h; air cool.
Hastelloy X	1175	2150	1	AC	Heat to 760 °C (1400 °F), hold 3 h; air cool; reheat to 595 °C (1100 °F), hold

(a) WQ, water quench; AC, air cool

Age-hardening practices for several nickel alloys are summarized in Table 4 and in the article "Heat Treating of Superalloys" in this Volume. In general, nickel alloys are soft when quenched from temperatures ranging from 790 to 1220 °C (1450 to 2225 °F); however, they may be hardened by holding at 480 to 870 °C (900 to 1600 °F) or above and then furnace or air cooling. Quenching is not a prerequisite to aging; the alloys can be hardened from the hot-worked and cold-worked conditions, as well as from the soft condition.

Hardening Techniques. Nickel alloy parts are sometimes hardened in sealed boxes placed inside a furnace, although small horizontal or vertical furnaces without boxes may be used also. The box or furnace should hold the parts loosely packed, yet afford a minimum of excess space. Electric furnaces with hot fans provide the optimum temperature uniformity of ±6 °C (±10 °F) and the freedom from contamination required for this work. Gas-heated furnaces, particularly those of the radiant-tube type, can be made so that they give satisfactory results. It is difficult to obtain good results from oil heating, even with muffle furnaces. All lubricants should be removed from the work before hardening.

Because of the long aging time and the difficulty of excluding air from the box or furnace, truly bright hardening cannot be accomplished commercially. For semibright hardening, dry hydrogen (see atmosphere 7 in Table 3) or cracked and dried ammonia (see atmosphere 4 in Table 3) should be used. Care should be exercised in the use and handling of these gases in the age-hardening temperature range that happens to span the minimum ignition temperature of hydrogen, 575 °C (1065 °F). When bright or semibright hardening is not required, other atmospheres may be used, such as nitrogen, cracked natural gas free of sulfur, cracked city gas, cracked hydrocarbons, or a generated gas. The use of sulfur-free gases is necessary to avoid embrittlement.

Salt baths are used occasionally for small parts. The hardened material is never bright and must be flash pickled to restore the natural color. Inorganic salts are used, such as chlorides and carbonates of sodium and potassium, which are relatively stable at temperatures considerably above their respective melting points. It is extremely important that the salts be free of all trace of sulfur so that the work does not become embrittled. Fluidized beds can also be used for this process and are viable substitutes for salt baths without the hazards of molten salts.

Heat-Resisting Alloys

Procedures for heat treating the nickel-base alloys used in turbine engines and for other high-temperature applications are described in the article "Heat Treating of Superalloys" in this Volume. Properties and applications of high-temperature nickel-base alloys can be found in Volumes 1 and 2 of *ASM Handbook*, formerly 10th Edition *Metals Handbook.*

Heat Treating of Titanium and Titanium Alloys

Revised by Roger Gilbert, IMI Titanium; and C. Richard Shannon, Teledyne Allvac

---

Introduction

TITANIUM AND TITANIUM ALLOYS are heat treated in order to:

- Reduce residual stresses developed during fabrication (stress relieving)
- Produce an optimum combination of ductility, machinability, and dimensional and structural stability (annealing)
- Increase strength (solution treating and aging)
- Optimize special properties such as fracture toughness, fatigue strength, and high-temperature creep strength

Various types of annealing treatments (single, duplex, β, and recrystallization annealing, for example), and solution treating and aging treatments, are imposed to achieve selected mechanical properties. Stress relieving and annealing may

be employed to prevent preferential chemical attack in some corrosive environments, to prevent distortion (a stabilization treatment), and to condition the metal for subsequent forming and fabricating operations.

Alloy Types and Response to Heat Treatment

The response of titanium and titanium alloys to heat treatment depends on the composition of the metal and the effects of alloying elements on the α-β crystal transformation of titanium. In addition, not all heat treating cycles are applicable to all titanium alloys, because the various alloys are designed for different purposes. Alloys Ti-5Al-2Sn-2Zr-4Mo-4Cr (commonly called Ti-17) and Ti-6Al-2Sn-4Zr-6Mo are designed for strength in heavy sections; Ti-6Al-2Sn-4Zr-2Mo and Ti-6Al-5Zr-0.5Mo-0.2Si, for creep resistance; Ti-6Al-2Nb-1Ta-1Mo and Ti-6Al-4V-ELI, for resistance to stress corrosion in aqueous salt solutions and for high fracture toughness; Ti-5Al-2.5Sn and Ti-2.5Cu, for weldability; and Ti-6Al-6V-2Sn, Ti-6Al-4V, and Ti-10V-2Fe-3Al, for high strength at low-to-moderate temperatures.

Effects of Alloying Elements on α-β Transformation. Unalloyed titanium is allotropic. Its close-packed hexagonal structure (α phase) changes to a body-centered cubic structure (β phase) at 885 °C (1625 °F), and this structure persists at temperatures up to the melting point.

With respect to their effects on the allotropic transformation, alloying elements in titanium are classified as α stabilizers or βstabilizers. Alpha stabilizers, such as oxygen and aluminum, raise the α-to-β transformation temperature. Nitrogen and carbon are also α stabilizers, but these elements usually are not added intentionally in alloy formulation. Beta stabilizers, such as manganese, chromium, iron, molybdenum, vanadium, and niobium, lower the α-to-β transformation temperature and, depending on the amount added, may result in the retention of some βphase at room temperature. Alloying elements such as zirconium and tin have essentially no effect on the α-to-β transformation temperature.

Alloy Types. Based on the types and amounts of alloying elements they contain, titanium alloys are classified as α, near-α, α-β, or βalloys (see, for example, the titanium alloy compositions listed in Volume 2 of *ASM Handbook*, formerly 10th Edition *Metals Handbook*). The response of these alloy types to heat treatment is briefly described below.

Alpha and near-alpha titanium alloys can be stress relieved and annealed, but high strength cannot be developed in these alloys by any type of heat treatment (such as aging after a solution beta treatment and quenching). Near-α alloys are alloys with predominantly a stabilizer, plus limited βstabilizers (normally, 2% or less).

The commercial βalloys are, in reality, metastable βalloys. When these alloys are exposed to selected elevated temperatures, the retained β phase decomposes and strengthening occurs. For β alloys, stress-relieving and aging treatments can be combined, and annealing and solution treating may be identical operations.

Alpha-beta alloys are two-phase alloys and, as the name suggests, comprise both αand β phases at room temperature. These are the most common and the most versatile of the three types of titanium alloys. Phase compositions, sizes, and distributions can be manipulated by heat treatment within certain limits to enhance a specific property or to attain a range of strength levels. A summary of typical heat treatments for α-β titanium alloys is given in Table 1.

Table 1 Summary of heat treatments for α-β Ti alloys

Heat treatment designation	Heat treatment cycle	Microstructure
Duplex anneal	Solution treat at 50-75 °C (90-135 °F) below Tβ[(a)], air cool and age for 2-8 h at 540-675 °C (1000-1250 °F)	Primary α, plus Widmanstätten α- βregions
Solution treat and age	Solution treat at ~40 °C (70 °F) below Tβ, water quench[(b)] and age for 2-8 h at 535-675 °C (995-1250 °F)	Primary α, plus tempered α' or a β- αmixture
Beta anneal	Solution treat at ~15 °C (30 °F) above Tβ, air cool and stabilize at 650-760 °C (1200-1400 °F) for 2 h	Widmanstätten α- βcolony microstructure

Beta quench	Solution treat at ~15 °C (30 °F) above T β, water quench and temper at 650-760 °C (1200-1400 °F) for 2 h	Tempered α'
Recrystallization anneal	925 °C (1700 °F) for 4 h, cool at 50 °C/h (90 °F/h) to 760 °C (1400 °F), air cool	Equiaxed α with β at grain-boundary triple points
Mill anneal	α - β hot work plus anneal at 705 °C (1300 °F) for 30 min to several hours and air cool	Incompletely recrystallized α with a small volume fraction of small β particles

Source: Ref 1

(a) T β is the β transus temperature for the particular alloy in question.

(b) In more heavily β -stabilized alloys such as Ti-6Al-2Sn-4Zr-6Mo or Ti-6Al-6V-2Sn, solution treatment is followed by air cooling. Subsequent aging causes precipitation of α phase to form an α- β mixture.

Beta transus temperatures for various commercial titanium alloys are listed in Table 2. When the heat treatment involves heating near the β transus, the transus temperature of each heat in a lot must be accurately determined.

Table 2 Beta transformation temperatures of titanium alloys

Alloy	**Beta transus**	
	°C, ± 15	**°F, ± 25**

(b) ±30.

(c) ±35.

(d) ±50

Titanium mill producers generally certify the βtransus temperature for each heat supplied. The β transus of a given alloy will vary from heat to heat due to small differences in chemistry, particularly oxygen content. Methods used for β transus determination are differential thermal analysis (DTA) and metallographic examination samples heated in 5 °C (10 °F) increments through the range of expected β transus. The DTA method has become the method of preference.

Oxygen and iron levels have significant effects on mechanical properties after heat treatment. It should be realized that:

- Oxygen and iron must be near specified maximums to meet strength levels in certain commercially pure grades
- Oxygen must be near a specified maximum to meet strength levels in solution-treated and aged Ti-6Al-4V
- Oxygen levels must be kept as low as possible to optimize fracture toughness. However, the oxygen level must be high enough to meet tensile strength requirements
- Iron content must be kept as low as possible to optimize creep and stress-rupture properties. Most creep-resistant alloys require iron levels at or below 0.05 wt%

Stress Relieving

Titanium and titanium alloys can be stress relieved without adversely affecting strength or ductility.

Stress-relieving treatments decrease the undesirable residual stresses that result from, first, nonuniform hot forging or deformation from cold forming and straightening, second, asymmetric machining of plate (hog-outs) or forgings, and, third, welding and cooling of castings. The removal of such stresses helps maintain shape stability and eliminates unfavorable conditions, such as the loss of compressive yield strength commonly known as the Bauschinger effect.

When symmetrical shapes are machined in the annealed condition using moderate cuts and uniform stock removal, stress relieving may not be required. Compressor disks made of Ti-6Al-4V have been machined satisfactorily in this manner, conforming with dimensional requirements. In contrast, thin rings made of the same alloy could be machined at a higher production rate to more stringent dimensions by stress relieving 2 h at 540 °C (1000 °F) between rough and final machining.

Separate stress relieving may be omitted when the manufacturing sequence can be adjusted to use annealing or hardening as the stress-relieving process. For example, forging stresses may be relieved by annealing prior to machining. Large, thin rings have been processed effectively with minimum distortion by rough machining in the annealed state, followed by solution treating, quenching, partial aging, finish machining, and final aging. Partial aging relieves quenching stresses, and final aging relieves stresses developed during finish machining.

Table 3 presents combinations of time and temperature that are used for stress relieving titanium and titanium alloys. The ranges in both time and temperature indicate that more than one combination may yield satisfactory results. The higher temperatures are usually used with shorter times, and the lower temperatures are used with longer times, for effective stress relief. During the stress relief of solution-treated and aged titanium alloys, care should be taken to prevent overaging to lower strength. This usually involves the selection of a time-temperature combination that provides partial stress relief. The parts, in bulk or in fixtures, may be charged directly into a furnace operating at the stress-relief temperature. If a part is mounted in a massive fixture, a thermocouple should be attached to the largest part of the fixture.

Table 3 Recommended stress-relief treatments for titanium and titanium alloys

Parts can be cooled from stress relief by either air cooling or slow cooling.

Figure 1 illustrates the effects of stress relieving Ti-6Al-4V at five temperatures ranging from 260 to 620 °C (500 to 1150 °F) for periods of time ranging from 5 min to 50 h.

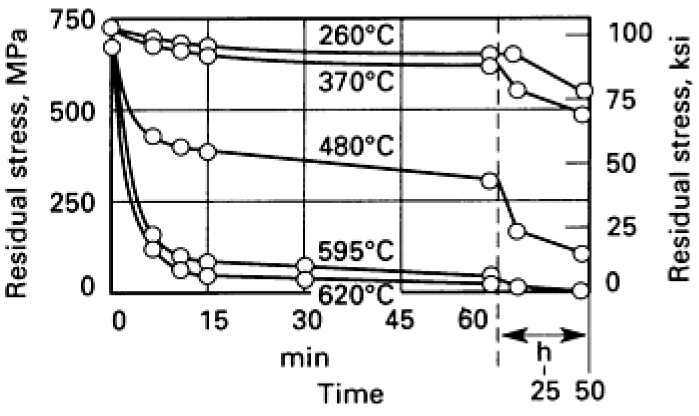

Fig. 1 Relationship between time and relief of residual stress at various temperatures for Ti-6Al-4V. Source: Ref 2

The rate of cooling from the stress-relieving temperature is not critical. Uniformity of cooling is critical, however, particularly in the temperature range from 480 to 315 °C (900 to 600 °F). Oil or water quenching should not be used to accelerate cooling because this can induce residual stresses by unequal cooling. Furnace or air cooling is acceptable.

Stress-relieving treatments must be based on the metallurgical response of the alloy involved. Generally, this requires holding at a temperature sufficiently high to relieve stresses without causing an undesirable amount of precipitation or strain aging in α-β and β alloys, or without producing undesirable recrystallization in single-phase alloys that rely on cold working for strength.

Stress relieving β alloys and the more highly alloyed α -β compositions should be done using a thermal exposure that is compatible with annealing, solution-treating, stabilization, or aging processes.

There are no nondestructive testing methods that can measure the efficiency of a stress-relief cycle other than the direct measurement of residual stresses by x-ray diffraction. No significant changes in microstructure due to stress-relieving heat treatments can be detected by optical microscopy.

Weldments. The temperatures used for stress relieving complex weldments of α or α-β alloys should be near the high ends of the ranges given in Table 3. Complex weldments may be defined as those having multiple welds in complex configurations, possibly involving combinations of machine and manual welding. In complex weldments made with commercially pure titanium, Ti-5Al-2.5Sn alloy or Ti-6Al-4V alloy, more than 70% of the residual stress is relieved during the first hour at temperature. Simple weldments of commercially pure titanium are often used without stress relief.

Annealing

The annealing of titanium and titanium alloys serves primarily to increase fracture toughness, ductility at room temperature, dimensional and thermal stability, and creep resistance. Many titanium alloys are placed in service in the annealed state. Because improvement in one or more properties is generally obtained at the expense of some other property, the annealing cycle should be selected according to the objective of the treatment.

Common annealing treatments are:

- Mill annealing
- Duplex annealing
- Recrystallization annealing
- Beta annealing

Recommended annealing treatments for several alloys are given in Table 4. Either air or furnace cooling may be used, but the two methods may result in different levels of tensile properties. If distortion is a problem, the cooling rate should be uniform down to 315 °C (600 °F). It may be difficult to prevent distortion of close-tolerance thin sections during annealing.

Table 4 Recommended annealing treatments for titanium and titanium alloys

Alloy	Temperature		Time, h	Cooling method
	°C	°F		
Commercially pure Ti (all grades)	650-760	1200-1400	$\frac{1}{10}$-2	Air

(a) For sheet and plate, follow by $\frac{1}{4}$ h at 790 °C (1450 °F), then air cool.

(b) For sheet, follow by $\frac{1}{4}$ h at 790 °C (1450 °F), then air cool (plus 2 h at 595 °C, or 1100 °F, then air cool, in certain applications). For plate, follow by 8 h at 595 °C (1100 °F) then air cool.

(c) Not normally supplied or used in annealed condition (see Table 3).

(d) Furnace or slow cool to 540 °C (1000 °F), then air cool.

Mill annealing is a general-purpose treatment given to all mill products. It is not a full anneal and may leave traces of cold or warm working in the microstructures of heavily worked products, particularly sheet.

Duplex annealing alters the shapes, sizes, and distributions of phases to those required for improved creep resistance or fracture toughness. In the duplex anneal of the Corona 5 alloy (Ref 3), for example, the first anneal is near the β transus to globularize the deformed α and to minimize its volume fraction. This is followed by a second, lower-temperature anneal to precipitate new lenticular (acicular) α between the globular α particles. This formation of acicular α is associated with improvements in creep strength and fracture toughness.

Recrystallization annealing and β annealing are used to improve fracture toughness. In recrystallization annealing, the alloy is heated into the upper end of the α-β range, held for a time, and then cooled very slowly. In recent years, recrystallization annealing has replaced β annealing for fracture-critical airframe components.

Beta Annealing. Like recrystallization annealing, β annealing improves fracture toughness. Beta annealing is done at temperatures above the β transus of the alloy being annealed. To prevent excessive grain growth, the temperature for β annealing should be only slightly higher than the β transus. Annealing times are dependent on section thickness and should be sufficient for complete transformation. Time at temperature after transformation should be held to a minimum to control β grain growth. Larger sections should be fan cooled or water quenched to prevent the formation of a phase at the β grain boundaries.

Straightening, sizing, and flattening of titanium alloys are often necessary in order to meet dimensional requirements. The straightening of bar to close tolerances and the flattening of sheet present major problems for titanium producers and fabricators.

Unlike aluminum alloys, titanium alloys are not easily straightened when cold because the high yield strength and modulus of elasticity of these alloys result in significant springback. Therefore, titanium alloys are straightened primarily by creep straightening and/or hot straightening (hand or die), with the former being considerably more prevalent than the latter.

Straightening, sizing, and flattening may be combined with annealing by the use of appropriate fixtures. The parts, in bulk or in fixtures, may be charged directly into a furnace operating at the annealing temperature. At annealing temperatures, many titanium alloys have a creep resistance low enough to permit straightening during annealing. With proper fixturing, and in some instances judicious weighting, sheet metal fabrication and thin, complex forgings have been straightened with satisfactory results. Again, uniform cooling to below 315 °C (600 °F) can improve results.

Straightening. Creep straightening may be readily accomplished during the annealing and/or aging processes of most titanium alloys. However, if the annealing/aging temperature is below about 540 to 650 °C (1000 to 1200 °F), depending on the alloy, the times required to accomplish the desired creep straightening can be extended. Creep straightening is accomplished with rudimentary or sophisticated fixtures and loading systems, depending on part complexity and the degree of straightening required. In hot hand or die straightening, which are used most frequently on small-to-intermediate-size parts, the parts are heated to the annealing or aging temperature, hot straightened, and then stress relieved at a temperature below that used during hot straightening.

Flattening. Various jigs and processing techniques have been proposed for annealing titanium in a manner that will yield a flat product. "Creep flattening" and "vacuum creep flattening" are two such techniques. Creep flattening consists of heating titanium sheet between two clean, flat sheets of steel in a furnace containing an oxidizing or inert atmosphere.

Vacuum creep flattening is used to produce stress-free flat plate for subsequent machining. The plate is placed on a large, flat ceramic bed that has integral electric heating elements. Insulation is placed on top of the plate, and a plastic sheet is sealed to the frame. The bed is slowly heated to the annealing temperature while a vacuum is pulled under the plastic. Atmospheric pressure is used to creep flatten the plate.

Stability. In α-β titanium alloys, thermal stability is a function of β-phase transformations. During cooling from the annealing temperature, β may transform and, under certain conditions and in β alloys, may form a brittle intermediate phase known as ω. A stabilization annealing treatment is designed to produce a stable β phase capable of resisting further transformation when exposed to elevated temperatures in service. Alpha-beta alloys that are lean in β, such as Ti-6Al-4V, can be air cooled from the annealing temperature without impairing their stability. Furnace (slow) cooling may promote the formation of Ti_3Al, an ordering reaction that can degrade resistance to stress corrosion. Slight increases in strength (up to 35 MPa, or 5 ksi) can be gained in Ti-6Al-4V and in Ti-6Al-6V-2Sn by cooling from the annealing temperature to 540 °C (1000 °F) at a rate of 55 °C/h (100 °F/h).

To obtain maximum creep resistance and stability in the near-α alloys Ti-8Al-1Mo-1V and Ti-6Al-2Sn-4Zr-2Mo, a duplex annealing treatment is employed. This treatment begins with solution annealing at a temperature high in the α-β range, usually 25 to 55 °C (50 to 100 °F) below the β transus for Ti-8Al-1Mo-1V and 15 to 25 °C (25 to 50 °F) below the β transus for Ti-6Al-2Sn-4Zr-2Mo. Forgings are held for 1 h (nominal) and then air or fan cooled, depending on section size. This treatment is followed by stabilization annealing for 8 h at 595 °C (1100 °F). Final annealing temperature should be at least 56 °C (100 °F) above the maximum anticipated service temperature. Maximum creep resistance can be developed in Ti-6Al-2Sn-4Zr-2Mo by β annealing or β processing.

Solution Treating and Aging

A wide range of strength levels can be obtained in α-β or β alloys by solution treating and aging. With the exception of the unique Ti-2.5Cu alloy (which relies on strengthening from the classic age-hardening reaction of Ti_2Cu precipitation similar to the formation of Guinier-Preston zones in aluminum alloys), the origin of heat-treating responses of titanium alloys lies in the instability of the high-temperature β phase at lower temperatures. Heating an α-β alloy to the solution-treating temperature produces a higher ratio of β phase. This partitioning of phases is maintained by quenching; on subsequent aging, decomposition of the unstable β phase occurs, providing high strength. Commercial β alloys, generally supplied in the solution-treated condition, need only be aged.

After being cleaned, titanium components should be loaded into fixtures or racks that will permit free access to the heating and quenching media. Thick and thin components of the same alloy may be solution treated together, but the time at temperature (soaking time) is determined by the thickest section. For most alloys, the rule is 20 to 30 min per inch (25 mm) of thickness to reach the required temperature, followed by the required soak time.

Time/temperature combinations for solution treating are given in Table 5. A load may be charged directly into a furnace operating at the solution-treating temperature. Although preheating is not essential, it may be used to minimize the distortion of complex parts.

Ti-15V-3Al-3Cr-3Sn	790-815	1450-1500	$\frac{1}{4}$	Air	510-595	950-1100	8-24

(a) For certain products, use solution temperature of 890 °C (1650 °F) for 1 h. then air cool or faster.

(b) Temperature should be selected from transus approach curve to give desired α content.

(c) For thin plate or sheet, solution temperature can be used down to 890 °C (1650 °F) for 6 to 30 min; then water quench.

(d) This treatment is used to develop maximum tensile properties in this alloy.

Solution treating of titanium alloys generally involves heating to temperatures either slightly above or slightly below the β transus temperature. The solution-treating temperature selected depends on the alloy type and practical considerations briefly described below.

Beta alloys are normally obtained from producers in the solution-treated condition. If reheating is required, soak times should be only as long as necessary to obtain complete solutioning. Solution-treating temperatures for β alloys are above the β transus; because no second phase is present, grain growth can proceed rapidly.

Alpha-Beta Alloys. Selection of a solution-treatment temperature for α-β alloys is based on the combination of mechanical properties desired after aging. A change in the solution-treating temperature of α-β alloys alters the amounts of β phase and consequently changes the response to aging (see Table 6).

Table 6 Variation of tensile properties of Ti-6Al-4V bar stock with solution-treating temperature

Solution-treating temperature	**Room.temperature tensile properties[(a)]**		**Elongation in 4*D*, %**
	Tensile strength	**Yield strength[(b)]**

870	1600	1060	154	985	143	17
900	1650	1095	159	995	144	16
925	1700	1110	161	1000	145	16
940	1725	1140	165	1055	153	16

(a) Properties determined on 13 mm ($\frac{1}{2}$ in.) bar after solution treating, quenching, and aging. Aging treatment: 8 h at 480 °C (900 °F), air cool.

(b) At 0.2% offset

To obtain high strength with adequate ductility, it is necessary to solution treat at a temperature high in the α-β field, normally 25 to 85 °C (50 to 150 °F) below the β transus of the alloy. If high fracture toughness or improved resistance to stress corrosion is required, β annealing or β solution treating may be desirable. However, heat treating α-β alloys in the β range causes a significant loss in ductility. These alloys are usually solution heat treated below the β transus to obtain an optimum balance of ductility, fracture toughness, creep, and stress-rupture properties. If the β transus is exceeded, tensile properties of α-β alloys (especially ductility) are reduced and cannot be fully restored by subsequent thermal treatment.

Near-Alpha Alloys. Like the α-β alloys, solution treatment above the β transus provides optimum creep resistance at the expense of reduced ductility and fatigue strength. To obtain the best combination of creep strength and fatigue strength, the solution temperature must be very close to but below the transus, so that only 10 to 15% of primary (untransformed) α remains. To be practical on the shop floor, a flattened β-approach curve is required so that temperature control is not as critical. In alloy IMI 834 this is achieved by the use of carbon additions (see the article "Wrought Titanium and Titanium Alloys" in Volume 2 of *ASM Handbook*, formerly 10th Edition *Metals Handbook*).

Quenching. The rate of cooling from the solution-treating temperature has an important effect on strength. If the rate is too low, appreciable diffusion may occur during cooling, and decomposition of the altered β phase during aging may not provide effective strengthening.

For alloys relatively high in β-stabilizer content and for products of small section size, air or fan cooling may be adequate; such slow cooling, where allowed by specified mechanical properties, is preferred because it minimizes distortion. Beta alloys are generally air quenched from the solution-treating temperature.

Water, a 5% brine, or caustic soda solution is preferred for quenching α-β alloys because these quenchants provide the cooling rates necessary to prevent the decomposition of the βphase obtained by solution treating, in order to provide maximum response to aging. The need for rapid quenching is further emphasized by short quench-delay requirements. Depending on the mass of the sections being heat treated, some α-β alloys can tolerate a maximum delay of 7 s, whereas more highly β-stabilized alloys can tolerate quench delay times of up to 20 s. The effect of quench delays on Ti-6Al-4V bar is shown in Fig. 2. When a Ti-6Al-4V section thickness exceeds 75 mm (3 in.), it is difficult to cool the center fast enough to maintain an unstable β phase. For this reason, the solution-treated and aged properties of Ti-6Al-4V large sections are similar to annealed properties. Less sensitive to delayed quenching are alloys such as Ti-6Al-2Sn-4Zr-6Mo, Ti-4Al-4Mo-2Sn-0.5Si, and Ti-5Al-2Sn-2Zr-4Mo-4Cr, in which fan air cooling develops good strength through 100 mm (4 in.) sections.

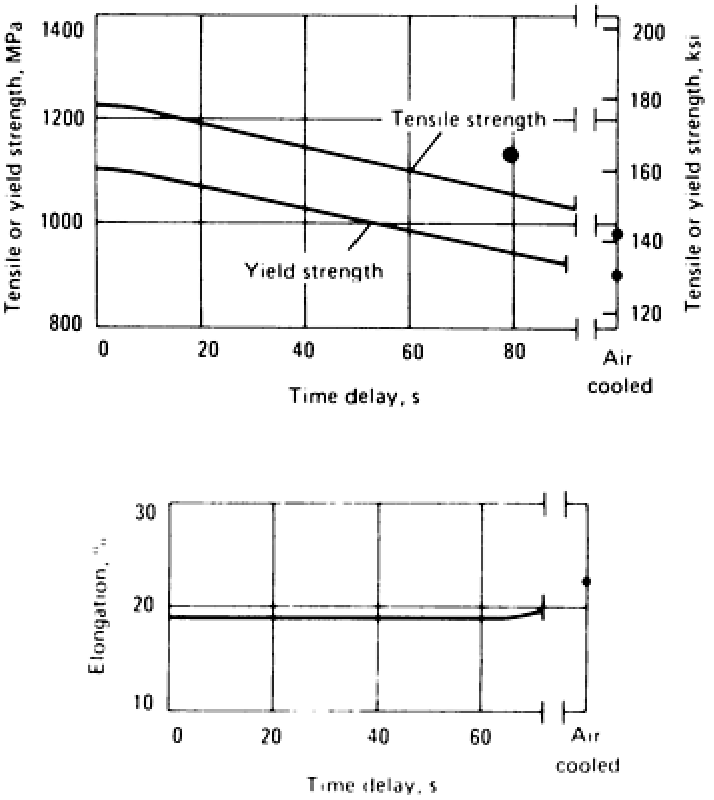

Fig. 2 Effects of quench delay on tensile properties of Ti-6Al-4V bar. Bar, 13 mm ($\frac{1}{2}$ in.) in diameter, was solution treated 1 h at 955 °C (1750 °F), water quenched, aged 6 h at 480 °C (900 °F), and air cooled. Source: Ref 4

Section size influences the effectiveness of quenching and, in turn, the response to aging. The amount and type of β stabilizer in the alloy determine the depth of hardening or strengthening. Thick sections exhibit lower tensile properties unless the alloy is highly alloyed with βstabilizers. The practical significance of section size for some alloys is given in Table 7. The effects of quenched section size on the tensile properties of Ti-6Al-4V alloy are shown in Fig. 3. The strength capabilities of solution-treated α-β alloys not highly β stabilized are greatly dependent on the oxygen content. The property levels for Ti-6Al-4V shown in Table 7 and Fig. 3 would be typical for an oxygen content between 0.17 and 0.20%. A lower oxygen content will tend to result in strength levels lower than those shown, particularly for the smaller section sizes.

Table 7 Relationship of tensile strength of solution-treated and aged titanium alloys to size

Alloy	Tensile strength of square bar in section size of

Aging. The final step in heat treating titanium alloys to high strength consists of reheating to an aging temperature between 425 and 650 °C (800 and 1200 °F). Aging causes the decomposition of the supersaturated β phase retained upon quenching. A summary of aging times and temperatures is presented in Table 5. The time/temperature combination selected depends on required strength. Aging at or near the annealing temperature results in overaging. This condition,

called solution treated and overaged, or STOA, is sometimes used to obtain modest increases in strength while maintaining satisfactory toughness and dimensional stability.

Although the aged condition is not necessarily one of equilibrium, proper aging produces high strength with adequate ductility and metallurgical stability. Heat treatment of α-β alloys for high strength frequently involves a series of compromises and modifications, depending on the type of service and the special properties required, such as ductility and suitability for fabrication. This has become especially true when fracture toughness is important in design and strength is lowered to improve design life.

During the aging of some highly β-stabilized α-β alloys, β transforms first to a metastable transition phase referred to as ω phase. Retained ω phase, which produces brittleness unacceptable in alloys heat treated for service, can be avoided by severe quenching and rapid reheating to aging temperatures above 425 °C (800 °F). However, because a coarse α phase forms, this treatment might not produce optimum-strength properties. An aging practice that ensures that aging time and temperature are adequate to carry out any ω reaction to completion is usually employed. Aging above 425 °C (800 °F) is generally adequate to complete the reaction.

The metastable β alloys do not require solution treatment. Final hot working, followed by air cooling, leaves these alloys in a condition comparable to a solution-treated state. In some instances, however, solution treating at 790 °C (1450 °F) has produced better uniformity of properties after aging. Aging at 480 °C (900 °F) for 8 to 60 h produces tensile strengths of 1.10 to 1.38 GPa (160 to 200 ksi). Aging for times longer than 60 h may provide higher strengths, but will decrease ductility and fracture toughness if the alloy contains chromium and titanium-chromium compounds are formed. Short aging times can be used on cold-worked material to produce a significant increase in strength over that obtained by cold working. The use of β alloys at service temperatures above 315 °C (600 °F) for prolonged periods is not recommended because the loss of ductility caused by metallurgical instability is progressive.

Other Special Thermal Treatments. Certain physical properties, such as notch strength, fracture toughness, and fatigue resistance, can be enhanced in some alloys by special thermal treatments. Three such treatments are:

- *Solution treating and overaging of Ti-6Al-4V:* Heat 1 h at 955 °C (1750 °F), water quench, hold 2 h at 705 °C (1300 °F), air cool. Advantages: improved notch strength, fracture toughness, and creep strength at strength levels similar to those obtained by regular annealing
- *Recrystallization annealing of Ti-6Al-4V or Ti-6Al-4V-ELI:* Heat 4 h or more at 925 to 955 °C (1700 to 1750 °F), furnace cool to 760 °C (1400 °F) at a rate no higher than 56 °C/h (100 °F/h), cool to 480 °C (900 °F) at a rate no lower than 370 °C/h (670 °F/h), air cool to room temperature. Advantages: improved fracture toughness and fatigue-crack-growth characteristics at somewhat reduced levels of strength
- *Beta annealing of Ti-6Al-4V, Ti-6Al-4V-ELI, Ti-6Al-2Sn-4Zr-2Mo, Ti-6Al-4V, or Ti-6Al-4V-ELI*: Heat 5 min to 1 h at 1010 to 1040 °C (1850 to 1900 °F), air cool to 650 °C (1200 °F) at a rate of 85 °C/min (150 °F/min) or higher, then heat 2 h at 730 to 790 °C (1350 to 1450 °F), air cool. Advantages: improved fracture toughness, high cycle fatigue strength and resistance to aqueous stress corrosion. Ti-6Al-2Sn-4Zr-2Mo: Heat $\frac{1}{2}$ h at 1020 °C (1870 °F), air cool, then hold 8 h at 595 °C (1100 °F), air cool. Advantages: improved creep strength at elevated temperatures and improved fracture toughness. Disadvantages: Beta annealing of α-β alloys produces relatively low tensile ductility. In recent years, recrystallization annealing has replaced β annealing for fracture-critical airframe components
- *High α-β solution treatment of Ti-5.8Al-4Sn-3.5Zr-O.7Nb-O.5Mo-0.3Si (IMI 834):* Determine β transus approach curve on small samples by quenching from temperature and plotting the percent of β phase against temperature. Choose solution treatment temperature to give 85 to 88% β. Heat 2 h at temperature, oil quench, age at 700 °C (1290 °F) for 2 h, air cool. Advantages: Excellent combination of creep and fatigue properties with good room-temperature tensile properties

Post-Heat-Treating Requirements. Titanium reacts with the oxygen, water, and carbon dioxide normally found in oxidizing heat treating atmospheres and with the hydrogen formed by the decomposition of water vapor. Unless the heat treatment is performed in a vacuum furnace or in an inert atmosphere, the oxygen will react with the titanium at the metal surface and produce an oxygen-enriched layer commonly called α case. This brittle layer must be removed before the

component is put into service. It can be removed by machining, but certain machining operations may result in excessive tool wear. Standard practice is to remove α case by other mechanical methods or by chemical methods, or both.

Oxidation rates of commercial titanium alloys vary, and Table 8 can be used as a guide to determine how much metal should be removed. Temperature and total time at temperature must be known. One method used to check for the complete removal of α case is to etch the component with a solution composed of 18 g of ammonium bifluoride per liter of water (2.4 oz/gal). The presence or absence of α case is detected by the difference in etching characteristics: Light gray shows the presence of α case; dark gray indicates its absence. If the component has been machined, as in the case of a forging, the ammonium bifluoride treatment must be preceded by etching in a solution consisting nominally of 5% HF, 30% min HNO_3, balance water. A more sensitive method for checking for α case is the etch-anodize, or "blue etch," technique. This method is described in SAE specification AMS 2642. For other mill products, such as plate, the microexamination of representative samples removed from the plate is commonly used.

(a) Values shown are typical; actual values may vary with alloy type.

Small amounts of hydrogen (100 to 200 ppm) can be tolerated in titanium alloys with the specific limiting amounts determined by the type of alloy. High hydrogen content can lead to premature failure of a component. Hydrogen pickup occurs not only during heat treatment but also during pickling or chemical cleaning operations used to remove α case. The amount of hydrogen pickup can be determined only by chemical analysis. If high hydrogen content is found, vacuum annealing is required. A typical vacuum annealing cycle consists of heating at or close to the annealing temperature for 2 to 4 h in a vacuum of ~10 μm.

Hardness testing is not recommended as a nondestructive method of checking the efficiency of heat treatment. The correlation between strength and hardness is poor. Whenever the verification of a property is required, the appropriate mechanical test should be used.

4. Properties and Processing Ti-6Al-4V, *Timet,* April 1980

Contamination during Heat Treatment

Before being subjected to any thermal treatment, titanium components should be cleaned and dried. *Caution: Do not use ordinary tap water in cleaning titanium components. Oil, fingerprints, grease, paint, and other foreign matter should be removed from all surfaces. Cleaning is required because the chemical reactivity of titanium at elevated temperatures can lead to its contamination or embrittlement and can increase its susceptibility to stress corrosion. After cleaning, parts should be handled with clean gloves to prevent recontamination. If a component is to be sized, straightened, or heat treated in a fixture, the fixture should be free of any foreign matter and loosely adhering scale.*

Titanium is chemically active at elevated temperatures and readily oxidizes in air. However, oxidation is not of primary concern in the heat treating of titanium, although it may be a problem in sheet-forming operations. Oxygen pickup during heat treatment results in both a surface structure composed predominantly of α phase and the formation of scale. This condition is detrimental because of the brittle nature of the oxygen-enriched α structure, which is also very abrasive to either carbide or high-speed-steel machine tools. For heat treatment in oxidizing atmospheres at 955 °C (1750 °F), the α structure can extend 0.2 to 0.3 mm (0.008 to 0.012 in.) below the surface and must be removed.

An antioxidant spray coating (see Example 2 in this article) may be applied to clean sheet metal parts in order to minimize oxygen pickup. Such coatings work effectively at temperatures up to about 760 °C (1400 °F), but their use does not fully eliminate the need for removing the surface structure after heat treating.

Hydrogen Pickup. Current specifications limit hydrogen content to a maximum of 125 to 200 ppm, depending on alloy and mill form. Above these limits, hydrogen embrittles some titanium alloys, thereby reducing impact strength and notch tensile strength and causing delayed cracking.

With the exceptions of high vacuum, salt baths, and chemically inert gases such as argon, all heat-treating atmospheres contain some hydrogen at temperatures used for annealing titanium. Hydrocarbon fuels produce hydrogen as a by-product of incomplete combustion, and electric furnaces with air atmospheres contain hydrogen from the breakdown of water vapor. However, because small amounts of hydrogen can be tolerated in titanium and because inert media are expensive, most titanium heat-treating operations are performed in conventional furnaces employing oxidizing atmospheres with at least 5% excess oxygen in the flue gas. The hydrogen absorption rate increases with temperature. Stress relieving, mill annealing, and aging all result in minimal hydrogen pickup. However, substantial hydrogen absorption can occur during solution treating or β annealing. Without a protective atmosphere, electric furnaces are recommended to minimize hydrogen pickup.

An oxidizing atmosphere serves to reduce hydrogen pickup in two ways: It reduces the partial pressure of hydrogen in the surrounding atmosphere, and it provides the titanium with a protective surface oxide that retards hydrogen pickup.

Oxidation rates of titanium alloys vary considerably. A comparison of the scaling rates of commercially pure titanium and titanium alloys in air at temperatures from 650 to 980 °C (1200 to 1800 °F) is given in Fig. 4. Table 9 indicates the measurable thickness of oxide formed on commercially pure titanium after $\frac{1}{2}$ h at various temperatures in air.

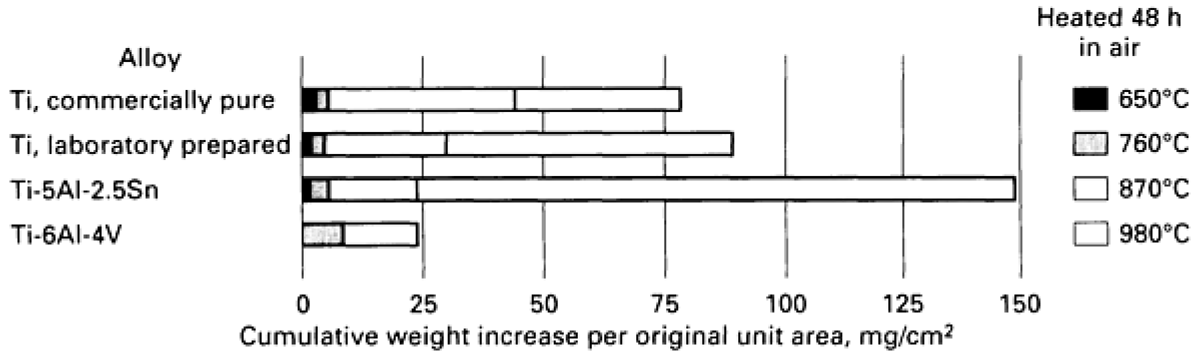

Fig. 4 Scaling rates of titanium and titanium alloys in air at various temperatures

Nitrogen is absorbed by titanium during heat treatment at a much slower rate than is oxygen and thus does not present a serious contamination problem. Dry nitrogen has been used successfully as a lower-cost protective atmosphere for heat treating titanium forgings that are to be fully machined after treatment. If absorbed in sufficient quantities, however, nitrogen forms a hard, brittle compound.

Carbon monoxide and carbon dioxide decompose in the presence of hot titanium and produce surface oxidation.

Chlorides. Titanium alloys are subject to stress corrosion when parts with high residual stress are exposed to chlorides at temperatures above 290 °C (550 °F). Salt from fingerprints, as well as the chlorides contained in some degreasing solutions, may cause stress-corrosion cracking at temperatures above 315 °C (600 °F). Although this phenomenon is readily produced in laboratory testing and is known to occur during heat treatment, hot-salt cracking has not been a significant problem in service. Care is required during thermal processing to ensure freedom from chloride contamination.

Growth during Heat Treatment

Solution treating of large parts requires allowances for growth during heat treatment. The growth due to heating may be retained after cooling, and this growth may be increased either by longer holding times at solution temperature or by lower heating rates. Table 10 gives examples of net growth of Ti-6Al-4V specimens heated to 955 °C (1750 °F).

Table 10 Effect of heating rate and time at 955 °C (1750 °F) on growth of Ti-6Al-4V

Mill heat[a]	Heating rate		Holding time[b], h	Net growth[c], %
	°C/min	°F/min		
A	3.3	6	0	0.27
B	3.3	6	0	0.22
A	3.3	6	1	0.60
B	3.3	6	1	0.49
A	3.3	6	2	1.00

B	3.3	6	2	0.90[(d)]
B	10	18	1	0.32
B[(e)]	10	18	1	0.35

Note: 50 mm (2 in.) specimens were taken in the longitudinal direction (except where otherwise indicated) from material annealed 2 h at 705 °C (1300 °F) and air cooled. No growth was observed in specimens tested during annealing.

(a) Beta transus temperatures (determined metallographically) were 990 °C (1810 °F) for heat A and 1015 °C (1860 °F) for heat B.

(b) All specimens water quenched after holding for time indicated.

(c) As determined by Leitz-Wetzler dilatometer.

(d) Calculated from curve.

(e) Specimen taken in transverse direction

Furnace Equipment and Accessories

Atmospheres. An oxidizing atmosphere should be maintained during any thermal treatment of titanium. Furnaces normally operated with exothermic atmospheres, endothermic cracked-ammonia atmospheres, or hydrogen atmospheres, because of the danger of hydrogen pickup, should be thoroughly "burned out" before being used for processing titanium. If dimensions, shape, or size do not permit the removal of scale by subsequent pickling or machining, antioxidant coatings suitable for use to 760 °C (1400 °F) can be employed to minimize contamination. A vacuum or an inert gas such as argon can also be used.

Furnaces. Titanium is usually annealed or stress relieved in conventional furnaces constructed for annealing steel. These furnaces are electric, gas fired, or oil fired, in order of decreasing popularity. The temperature-control equipment for these operations should have an accuracy of ±5 °C (±10 °F) and should be capable of controlling and recording the desired temperature within ±15 °C (±25 °F), except when control with ±10 °C (±15 °F) is required by MIL-H-81200.

Vacuum annealing furnaces are either of the cold-wall or the hot-wall type and may be heated by gas or electricity.

Cold-wall electric vacuum furnaces are used most commonly with titanium. Maximum furnace operating temperature depends on the heating elements and radiation shields, but usually these furnaces are designed for a maximum temperature of 980 °C (1800 °F) and are adequate for all titanium alloys. Hot-wall electric furnaces and gas-fired vacuum furnaces have been used in production. When the furnace employs a metallic retort, operating temperatures are held below 980 °C (1800 °F); higher temperatures can be achieved with ceramic retort tubes.

Laboratory vacuum annealing furnaces are usually operated at pressures of 0.1 μm or less, whereas production furnaces are designed to operate at pressures of 0.5 to 3.0 μm.

Vacuum annealing is expensive and is generally used only when a reduction in hydrogen content is required, further hydrogen contamination is prohibited, or allowances that can be made for stock removal are insufficient to permit surface contamination resulting from annealing in air. Hydrogen outgassing at 705 °C (1300 °F) and below is so slow that its cost may be prohibitive. A temperature of 730 °C (1350 °F) is recommended as a minimum, and temperatures from 760 to 790 °C (1400 to 1450 °F) are preferred. At a temperature of 760 °C, the removal of 100 ppm of hydrogen from 13 to 25 mm

($\frac{1}{2}$ to 1 in.) sections of Ti-6Al-4V alloy required approximately 2 h at a pressure of <10 μm. Actual time at temperature may vary widely depending on the capability of the furnace to maintain a vacuum.

Solution-treating equipment can vary from a simple furnace with accurate temperature control and a water quench tank to specialized installations for treating complex parts. Electrically heated furnaces are preferred because they minimize hydrogen pickup, although fuel-fired furnaces with slightly oxidizing conditions or with muffles that protect the metal from combustion products have been used successfully. Also, resistance and induction heating have been used to reduce heating times and to minimize contamination during solution treatment. Accuracy of temperature control equipment should be within ±3 °C (±5 °F), and the desired temperature should be controlled within ±15 °C (±25 °F).

To reduce distortion in long, thin products such as sheet or extrusions; in hollow cylinders; and in long forgings during immersion quenching, parts are often suspended vertically in an electrically heated drop-bottom furnace. In addition, weights are usually attached to the bottom ends of sheet to improve flatness during heating and to facilitate lowering of the sheet into the quench tank.

Quenching Media. Because rapid cooling is required after the solution treatment of most titanium alloys, either water or a 5% brine or caustic soda solution is most widely used as the quenching medium. Low-viscosity oil with a high flash point has been used effectively in vertical immersion quenching of sheet to reduce distortion. Quenching oils used with steel provide rapid cooling to 370 to 425 °C (700 to 800 °F), and these oils are satisfactory. Their use, however, should be limited to thin sections to avoid the degradation of strength compared to that obtained by water quenching from the same solution temperature. Various concentrations of glycol in water will produce quench rates between those of water and those of oil. During quenching, the quench media should be thoroughly agitated. Recirculating systems are preferred, with the quench media maintained at temperatures below 40 °C (100 °F).

Aging Furnaces. Because they do not involve combustion by-products, furnaces of the electrical-resistance type are preferable for aging titanium and its alloys. Retorts, however, may be used with oil-fired or gas-fired furnaces to avoid contamination. Aging furnaces are normally equipped with internal fans to promote the circulation of air or other atmosphere throughout the work zone. Temperature control equipment should be accurate to ±1 °C (±2 °F) and should be capable of controlling temperature within ±10 °C (±15 °F).

At normal aging temperatures of 480 to 595 °C (900 to 1100 °F), a protective atmosphere is not required. Aging in air produces a superficial scale that can be removed easily by mechanical or chemical means (this scale also may be left in place because it does not affect properties).

Fixtures. In fixturing titanium components or assemblies to prevent distortion, the thermal-expansion characteristics of both the titanium alloy and the fixture itself must be considered. Ideally, both the alloy and the fixture will have equivalent thermal expansion characteristics within the intended aging-temperature range. Mild steel is commonly used because it is low in cost and can be made reasonably resistant to oxidation at aging temperatures through the use of coatings such as electroless nickel. When mild steel fixtures are used, allowance must be made for the slight difference between the thermal expansion of the mild steel and that of titanium to avoid undesirable growth or distortion of the treated part.

In some applications, it is necessary to reduce or eliminate existing distortion in a part or assembly. This distortion may have resulted from water quenching, from relief of residual stresses during machining, from stresses induced by welding, or from uncontrollable springback after forming. Proper fixturing during aging can be used to minimize such distortion. Fixtures also must guard against sagging. For example, Ti-6Al-4V has a tendency to sag at 955 °C (1750 °F) during solution heat treating. Because titanium alloys exhibit creep behavior within the normal range of aging temperatures, it is possible to fixture and "creep form" components or assemblies to desired shape. Parts may also be sized by fixturing during aging.

Summary of Practice. Key considerations in the heat treating of titanium and its alloys--practices that are to be followed and those that should be avoided--are:

- Provide sufficient stock for post-treatment metal-removal requirements (contaminated metal removal)
- Clean components, fixtures, and furnaces prior to heat treatment. *Caution: (Do not use ordinary tap water to clean titanium components)*
- Do not allow temperature to exceed β transus (unless it is specified as a β anneal process). Use

temperature controls with an upper cutoff at least 15 °C (25 °F) below β transus

- Charge cold components into furnaces operating at the required temperature
- Stack and support components to allow free access of heating and quenching media. Do not nest components
- Observe quench-delay requirements to ensure a hardening response during aging
- Review property requirements and select optimum heat-treating procedure
- Review strength requirements and select proper aging cycle
- Remove α case after all heat treating is completed
- Check for the presence of hydrogen after all processing is completed
- Do not rely on inert atmosphere or vacuum for the prevention of oxygen contamination
- Ensure that a reliable β transus temperature is known and reviewed for each heat of product before treating at temperatures high in the α-β range
- Realize the significant effect of oxygen and iron on the mechanical property response after heat treatment. (See the section "Oxygen and Iron Levels" in this article)
- Do not rely on hardness tests for a measurement of the effects of heat treatment
- Do not pickle assemblies with faying surfaces

Production Examples of Heat-Treating Processes

The examples that follow describe applications of heat-treating processes to specific titanium parts and assemblies and indicate typical relationships among heat treating and other production operations.

Example 1: Heat Treatment of Welded α-Alloy Compressor Cases.

Because α alloys are not hardenable, the heat treatment of welded compressor cases made of α alloy Ti-5Al-2.5Sn was limited to annealing and stress relieving. After the subassemblies had been formed, machined, and stress relieved, the cases were assembled using manual and mechanized inert-gas-shielded tungsten arc welding and resistance welding. The completed assemblies were stress relieved for 1 h at 620 °C (1150 °F) in an electric muffle furnace with air atmosphere. Neither fixturing nor protective coating was used. After being stress relieved, the cases were descaled by grit blasting and light pickling in a nitric-hydrofluoric acid solution.

Example 2: Heat Treatment of Welded Ti-6Al-4V Wing Ribs.

After being inert-gas-shielded tungsten arc welded with Ti-6Al-4V filler rod, a wing rib made of annealed Ti-6Al-4V sheet was solution treated for 1 h at 900 °C (1650 °F) in an air muffle furnace and water quenched. The part was protected by a glass coating during heating. (The coating, which consisted of hydrous borax, boric acid, and aluminum hydrate in a volatile carrier, was sprayed on the sheet at a dry weight of 269 to 323 g/m^2, or 0.88 to 1.06 oz/ft^2.) After being quenched, the part was inserted in an aging fixture and forced into the desired shape. It was aged in the fixture for 4 h at 540 °C (1000 °F) in an air muffle furnace. Sufficient relaxation and relief of stresses occurred during aging to bring the part into conformity with dimensional requirements. After aging, the welds had an ultimate tensile strength of 1090 MPa (158 ksi), a yield strength of 985 MPa (143 ksi), and 6% elongation in 13 mm ($\frac{1}{2}$ in.).

It should be noted that in this example, the development of maximum properties in α-β alloy weldments required solution treating, followed by rapid quenching and then aging. However, if reduced strength were acceptable or higher ductility were required, workpieces could have been simply annealed after welding.

Example 3: Ti-6Al-4V Pressure Vessel.

A spherical pressure vessel 610 mm (24 in.) in diameter and 6.4 mm ($\frac{1}{4}$ in.) in wall thickness was fabricated from 19 mm ($\frac{3}{4}$ in.) thick hemispherical forgings of Ti-6Al-4V. The hemispheres were rough machined and tack welded to a special frame mounted on the lid of a cylindrical electric furnace. The rough-machined hemispheres were then solution treated for 1 h in argon at 900 °C (1650 °F), water quenched, and finish machined. Furnace loading and unloading were accomplished by the use of an overhead crane, and the parts were quenched within 6 s after being removed from the

furnace. The two hemispheres were joined by mechanical inert-gas-shielded tungsten arc welding using Ti-6Al-4V titanium filler metal and reinforced weld area. Following welding, the vessel was aged for 6 h in a circulating-air furnace at 540 °C (1000 °F). Neither fixturing nor protective coating was used. Cleaning after aging consisted of pickling in nitric-hydrofluoric acid solution.

Example 4: Ti-5Al-2.5Sn Turbojet Compressor Case.

Figure 5 shows a 760 mm (30 in.) diam jet engine compressor case that was fabricated from Ti-5Al-2.5Sn. The shell of the case was roll formed into two half-round segments after the ports had been punched. After rolling, the ports were drawn in resistance-heated dies at 595 °C (1100 °F). After being loaded in stainless steel fixtures, the half-round segments were stress relieved in an air muffle furnace for 1 h at 620 °C (1150 °F). The ports were then sized to final dimensions while the curvature of the segments was maintained with a fixture. After the ports had been drawn and the segments stress relieved, all components were cleaned by grit blasting and pickling. The half-round segments were then welded by the inert-gas-shielded tungsten arc method, and the resulting weldments were stress relieved for 1 h at 620 °C (1150 °F) without fixturing.

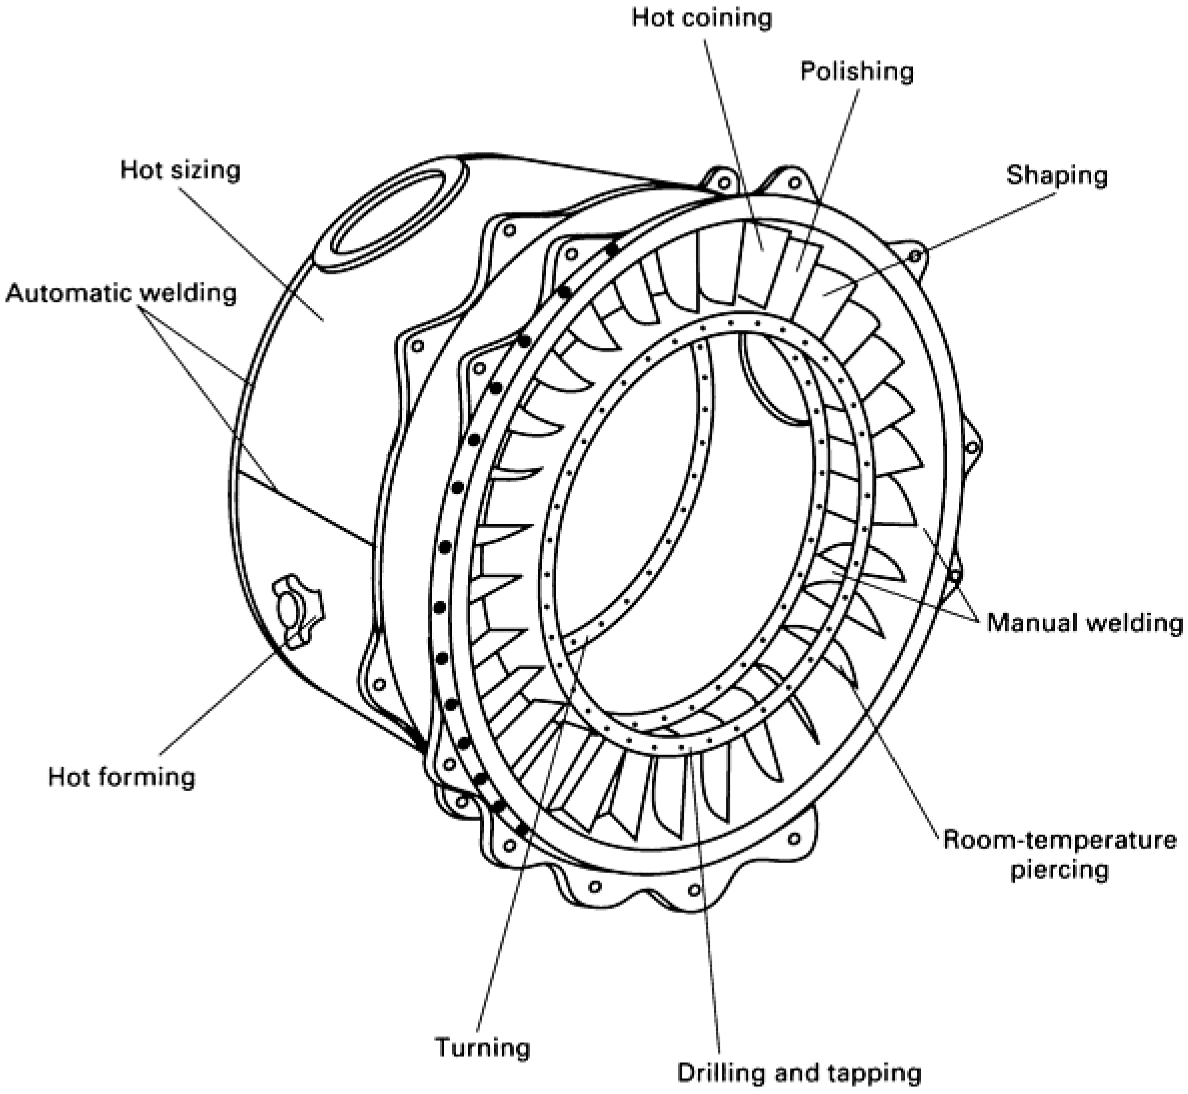

Fig. 5 Turbojet compressor case, showing fabrication processes employed in its manufacture

The shrouds were brake formed to a radius of 2.5 *t* at room temperature. Between brake-forming operations, the shrouds were resistance heated in air at 595 °C (1100 °F) for 5 min. Following brake forming, the shrouds were wrap formed to their final diameters at 120 °C (250 °F) in heated dies to reduce springback. They were then stress relieved 1 h at 620 °C (1150 °F) in air, and air cooled. No fixturing was necessary for maintaining tolerances.

The vanes were fabricated from machined bar stock and sheet. The annealed material was welded to form hollow vanes and then hot coined at 650 °C (1200 °F) in dies to flatten the parts and relieve welding stresses. Following coining, the vanes were cleaned and machined to an airfoil contour.

The final assembly was made by joining the various stress-relieved components by fusion welding. After assembly, the entire compressor case was stress relieved (without fixturing) in an air furnace for 1 h at 620 °C (1150 °F) and air cooled. Then the assembly was cleaned by grit blasting and pickling.

Example 5: Ti-6Al-4V Wing Section.

Skins of Ti-6Al-4V were stretched formed at room temperature in the fully annealed condition and solution treated in air for 30 min at 900 °C (1650 °F). After being water quenched, the distorted parts were placed in a steel aging frame and clamped to make them conform to the desired configuration. The skins and fixtures were aged 4 h at 540 °C (1000 °F) in a muffle furnace. Relaxation during aging was sufficient to bring the skins within drawing tolerances.

Example 6: Extruded Ti-6Al-4V T-Section Wing Section.

Ti-6Al-4V wing sections (1.22 m, or 48 in., long) for spars were hung vertically on a rack for solution treatment in an air muffle furnace at 900 °C (1650 °F). The rack and the parts were then rapidly quenched in water. Straightening the distorted (primarily, bowed) extrusions was accomplished by the use of fixtures during aging. The parts were subjected to a 50% overbend by insert spacers and aged 4 h at 540 °C (1000 °F) before being machined. This aging cycle was repeated after each of the three required machining operations. Heat treating was performed without protective atmosphere. After the solution treatment and the first aging treatment, the parts were pickled in nitric-hydrofluoric acid solution. Pickling removed the contaminated surface layer and increased tool life in machining.

Example 7: Ti-6Al-4V Rocket Motor Cases.

In the fabrication of rocket motor cases made of Ti-6Al-4V, the individual components were machined to a maximum wall thickness of 12.7 mm (0.500 in.), or to 7.62 mm (0.300 in.) wherever possible, allowing at least 1.3 mm (0.050 in.) of stock for cleanup after solution treating. Only cylindrical components were placed in fixtures for the solution-treating operation. Solution treating was performed by holding the parts for 2 h at a temperature 19 to 33 °C (35 to 60 °F) below the β transus (aim: 28 °C, or 50 °F, below β transus) in a bottom-loading gantry furnace and then quenching them rapidly in a violently agitated 3% solution of sodium hydroxide.

Tensile test coupons, representative of all parts in the load, were heated and quenched with the work. Before the parts themselves were aged, the test coupons were aged for 8 h at each of four temperatures--480, 510, 540, and 565 °C (900, 950, 1000, and 1050 °F)--to determine the optimum aging temperature in terms of desired mechanical properties. Then the parts were fixtured (a predetermined load was applied to promote creep forming), aged 8 h at optimum temperature, and air cooled. The use of a protective atmosphere was not required.

After being aged, the components were machined to final dimensions before welding in order to remove surface material that had been oxidized and contaminated during solution treating. Components were then welded into the final assemblies without preheating or postheating. The completed assemblies were stress relieved for 2 h at 480 °C (900 °F) and air cooled.

Heat Treating of Tin-Rich Alloys

Revised by William B. Hampshire, Tin Information Center

Introduction

IN HEAT TREATING of tin-rich alloys, it is difficult to secure an effective and permanent degree of hardening. Tin melts at 232 °C (505 K), and therefore room temperature (about 295 K) is well over one-half the absolute melting point. It follows that high-temperature behavior such as recrystallization and recovery can occur in fairly short times, even at room temperature. Tin is also an unusual metal because it can work soften under certain conditions, and so heat treating can be used in these cases to restore some of the original hardness and strength.

Heat treating of tin-rich alloys has been practiced for bearing alloys, pewterware, and organ pipe alloys. Some of the principles underlying these applications will be reviewed first.

Binary Alloys

Tin-antimony, tin-bismuth, tin-lead, and tin-silver alloys can all be temper hardened by solution treatment and aging. However, only the tin-antimony alloys can be permanently strengthened by heat treatment; all other tin-rich binary alloys will gradually soften at room temperature. The greatest improvement obtainable in binary tin-antimony alloys occurs in the alloy that contains 9% Sb; a hardness of 21 HB and a tensile strength of 51 MPa (7.4 ksi) can be increased to 26 HB and 65 MPa (9.4 ksi). This alloy is tempered for 48 h at 100 °C (212 °F) after being quenched from 225 °C (435 °F). During this tempering treatment, ductility decreases from 20 to 10% elongation (in 50 mm, or 2 in.).

Ternary Alloys

Permanent effects produced by heat treatment also carry over into ternary alloys of tin, antimony, and cadmium. This was discovered during an early investigation of the strength and hardness of ternary alloys containing up to 43% Cd and 14% Sb using chill-cast specimens. It was found that the strengthening effect of cadmium in the terminal solution tin phase (alpha) is much greater than that of antimony. In this study, the maximum stable values obtained in alloys containing 7 to 9% Sb and 5 to 7% Cd were as follows: tensile strength, 108 MPa (15.7 ksi); elongation, 15% (in 50 ram, or 2 in.); and hardness, 35 HB. The presence of the sigma phase (principally SbSn) as primary cuboids had no effect on strength or hardness, but the presence of primary epsilon (CdSb) destroyed the useful mechanical properties. Therefore, alloys containing cadmium generally use compositions that restrict the formation of the primary (CdSb) epsilon phase. The maximum combination of strength, ductility, and hardness is obtained in alloys that have finely dispersed precipitates of the sigma and epsilon phases in an alpha matrix, or finely dispersed epsilon in a matrix of alpha with a eutectoid of alpha plus gamma (cadmium-rich solid solution). These structures are typically achieved by quenching or rapid cooling from elevated temperatures to avoid precipitation of primary sigma and epsilon.

Additional heat-treatment studies have been directed to a group of cold-workable tin-rich alloys containing 3 to 8% Cd and 1 to 9% Sb. Two forms of hardening were observed on quenching of these alloys from 185 to 200 °C (365 to 390 °F). One form results from the change in solubility of antimony in tin or in the beta phase. The other, which produces more intensive hardening, is analogous to hardening of binary cadmium-tin alloys by quenching and depends on suppression of eutectoid decomposition of the beta phase. Permanent improvement results in the first instance. Therefore, a maximum tensile strength of 101 MPa (14.6 ksi) was achieved in a Sn-3Cd-7Sb alloy that was quenched from 190 °C (375 °F) and then aged for either 24 h at 100 °C (212 °F) or 18 months at room temperature.

Further studies have been carded out on tin-base alloys containing 7 to 10% Sb and 0 to 3% Cd in an effort to locate a bearing alloy that would be suitable at mildly elevated temperatures. In this composition range, it was found that alloys containing 0.5 to 2% Cd (but not 3%) can be strengthened considerably by quenching and tempering.

Optimum properties (tensile strength: 92 MPa, or 13.4 ksi) were obtained in a Sn-9Sb-1.5Cd alloy quenched from 220 °C (430 °F) and then aged for 1000 h at 140 °C (285 °F). This alloy consists of finely divided sigma and epsilon phases in a matrix of alpha.

Pewter

Many pewter articles are manufactured from sheet prepared by cold reduction of cast bars or slabs. Tin-rich pewter alloys containing antimony and copper will work harden during sheet-rolling operations that involve small percentage reductions (20%). If left standing at room temperature, the alloy will recrystallize and soften until it has reverted to the hardness of the original cast bar or slab. On the other hand, if large reductions (such as 90%) are made and the crystals are heavily worked, the alloy will work soften. Then, as crystals increase in size, hardness increases slightly, but never to the level of the original cast material.

The hardness values of spun pewterware, or of other articles that have been manufactured by mechanically working the metal, can be restored by heat treatment at temperatures from 110 to 150 °C (230 to 300 °F). The time required varies from 3 h at the lower temperature to a few minutes at the higher temperature. A tin alloy containing 6% Sb and 2% Cu hardens to 90% of the hardness of the as-cast material after annealing for 1 h at 200 °C (390 °F). Longer annealing times at lower temperatures have smaller but similar effects on the recovery from work softening.

Introduction

LEAD is normally considered to be unresponsive to heat treatment. Yet, some means of strengthening lead and lead alloys may be required for certain applications. Lead alloys for battery components, for example, can benefit from improved creep resistance in order to retain dimensional tolerances for the full service life. Battery grids also require improved hardness to withstand industrial handling.

The absolute melting point of lead is 327.4 °C (621.3 °F). Therefore, in applications in which lead is used, recovery and recrystallization processes and creep properties have great significance. Attempts to strengthen the metal by reducing the grain size or by cold working (strain hardening) have proved unsuccessful. Lead-tin alloys, for example, may recrystallize immediately and completely at room temperature. Lead-silver alloys respond in the same manner within two weeks.

Transformations that are induced in steel by heat treatment do not occur in lead alloys, and strengthening by ordering phenomena, such as in the formation of lattice superstructures, has no practical significance.

Despite these obstacles, however, attempts to strengthen lead have met with some success.

Solid-Solution Hardening

In solid-solution hardening of lead alloys, the rate of increase in hardness generally improves as the difference between the atomic radius of the solute and the atomic radius of lead increases.

Specifically, in one study of possible binary lead alloys it was found that the following elements, in the order listed, provided successively greater amounts of solid-solution hardening: thallium, bismuth, tin, cadmium, antimony, lithium, arsenic, calcium, zinc, copper, and barium. Unfortunately, these elements have successively decreasing solid-solution solubilities, and therefore the most potent solutes have the most limited solid-solution hardening effects. Within the midrange of this series, however, are elements that, when alloyed with lead, produce useful strengthening.

A useful level of strengthening normally requires solute additions in excess of the room-temperature solubility limit. In most lead alloys, homogenization and rapid cooling result in a breakdown of the supersaturated solution during storage. Although this breakdown produces coarse structures in certain alloys (lead-tin alloys, for example), it produces fine structures in others (such as lead-antimony alloys). In alloys of the lead-tin system, the initial hardening produced by alloying is quickly followed by softening as the coarse structure is formed.

At suitable solute concentrations in lead-antimony alloys, the structure may remain single phase with hardening by Guinier-Preston (GP) zones formed during aging. At higher concentrations, and in certain other systems, aging may produce precipitation hardening as discrete second-phase particles are formed.

Alloys that exhibit precipitation hardening typically are less susceptible to overaging and therefore are more stable with time than alloys hardened by GP zones. Lead-calcium and lead-strontium alloys have been observed to age harden through discontinuous precipitation of a second phase--Pb_3Ca in lead-calcium alloys and Pb_3Sr in lead-strontium alloys--as grain boundaries move through the structure.

Solution Treating and Aging

Useful strengthening of lead can be attained by adding sufficient quantities of antimony to produce hypoeutectic lead-antimony alloys. Small amounts of arsenic have particularly strong effects on the age-hardening response of such alloys, and these effects are enhanced by solution treating and rapid quenching prior to aging.

An investigation (Ref 1) was conducted on the effects of additions of 0.15% arsenic on the age-hardening behavior of five hypoeutectic lead-antimony alloys. Accurately weighed quantities of commercially pure lead, antimony, and arsenic were melted under a nitrogen atmosphere to produce the alloys listed below:

Alloy	Antimony, %	Arsenic, %
200	2.0	. . .
215	2.0	0.15
400	4.0	. . .
415	4.0	0.15
600	6.0	. . .
615	6.0	0.15
800	8.0	. . .
815	8.0	0.15
1000	10.0	. . .
1015	10.0	0.15

To minimize segregation during solidification, the melts, each weighing about 100 g (3.5 oz), were chilled rapidly by casting into a shallow horizontal steel boat. Pieces weighing about 15 g (0.5 oz) were cut from the castings and were used as hardness test specimens after being subjected to one of two heat treatments. One group of specimens, designated group A, was air cooled from the liquid state and quenched in ice water as soon as solidification was complete. Another group, designated group B, was solution treated for 4 h at 250 °C (480 °F) and then quenched in ice water.

In view of the rapid age hardening of the arsenical alloys, commencing the hardness tests as soon after quenching as possible was desirable, and one minute was chosen as a reasonable period. For group B specimens, this was easily achieved by solution treating the specimens, which had previously been ground with 600-grade paper, in a stream of nitrogen in a vertical tube furnace. The specimens were then dropped into ice water and transferred after 20 s to water at room temperature. Hardness of these specimens was measured with a Vickers hardness tester using a 2.5 kg load.

Because the specimens in group A could not be prepared for hardness testing before they were quenched, a different procedure was necessary to permit testing to commence after 1 min. These specimens were remelted in small flat-based cylindrical cups punched from thin aluminum foil. After quenching, the foil was peeled from the specimen and the hardness measurement was made on the flat surface (after the top surface had been quickly smoothed on a file to ensure proper seating in the test machine).

Cooling curves were obtained for the specimens in group A by means of Chromel-Alumel thermocouples, which were thinly sheathed with mild steel. After remelting, the thermocouple was removed before the beginning of solidification. Quenching then was timed to follow complete solidification on the basis of the previous cooling curves. The group A specimens were cooled at a rate of 1 °C/s (1.8 °F/s) to solidification at 232 °C (450 °F). These specimens showed evidence of surface segregation.

Hardness tests were continued for up to two years, with the specimens being stored at ambient temperature, which for the majority of the time was between 20 and 22 °C (68 and 72 °F). To investigate variations in hardness, tests were made on some of the specimens using a Reichert microhardness tester (5.3 g load, applied for 10 s).

Test Results. Results of hardness testing showed that lead-antimony alloys of commercial purity demonstrate significant age hardening, particularly after solution treating, as shown in Fig. 1 and 2. In the quench-cast alloys of group A, the hardness at any time increased with antimony content. For the solution-treated specimens of group B, aging was more effective for alloys with lower antimony contents.

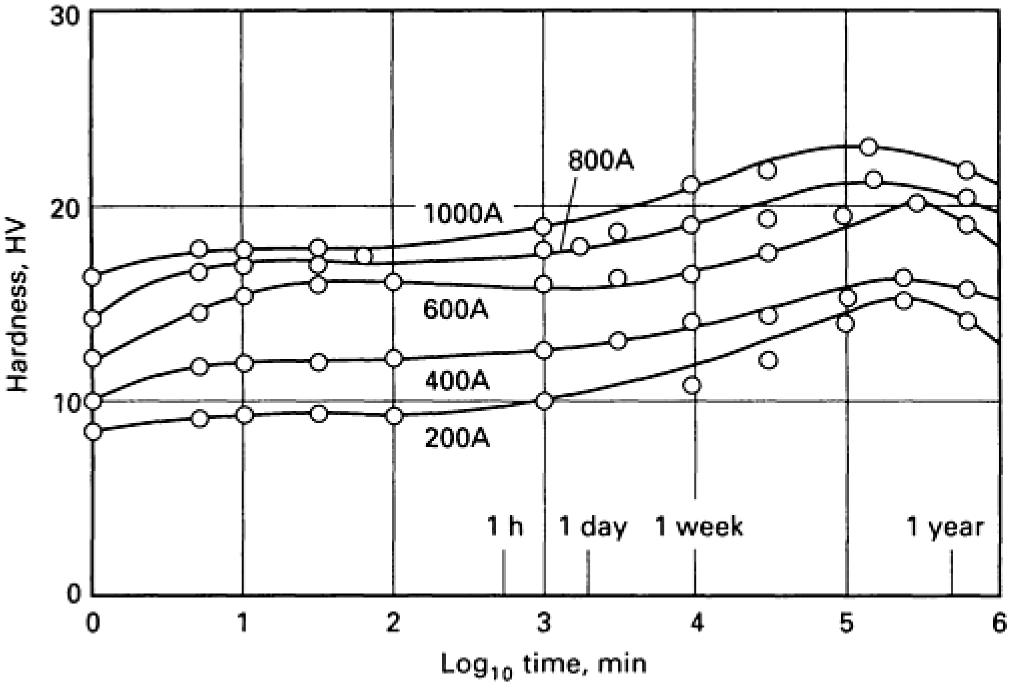

Fig. 1 Age hardening of lead-antimony alloys, solidified and water quenched

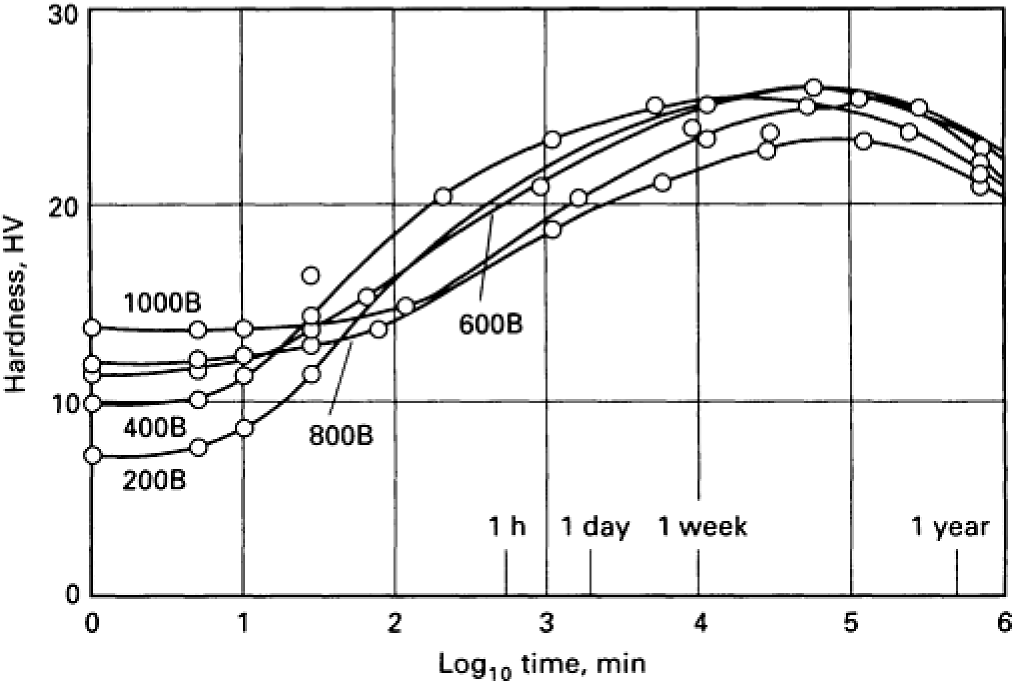

Fig. 2 Age hardening of lead-antimony alloys, solution treated 4 h at 250 °C (480 °F) and water quenched

Figures 3 and 4 show that both the rate and the extent of hardening are increased by addition of 0.15% As. As shown in Fig. 4, increases in hardness of the solution-treated hypoeutectic alloys are pronounced in the first 10 min.

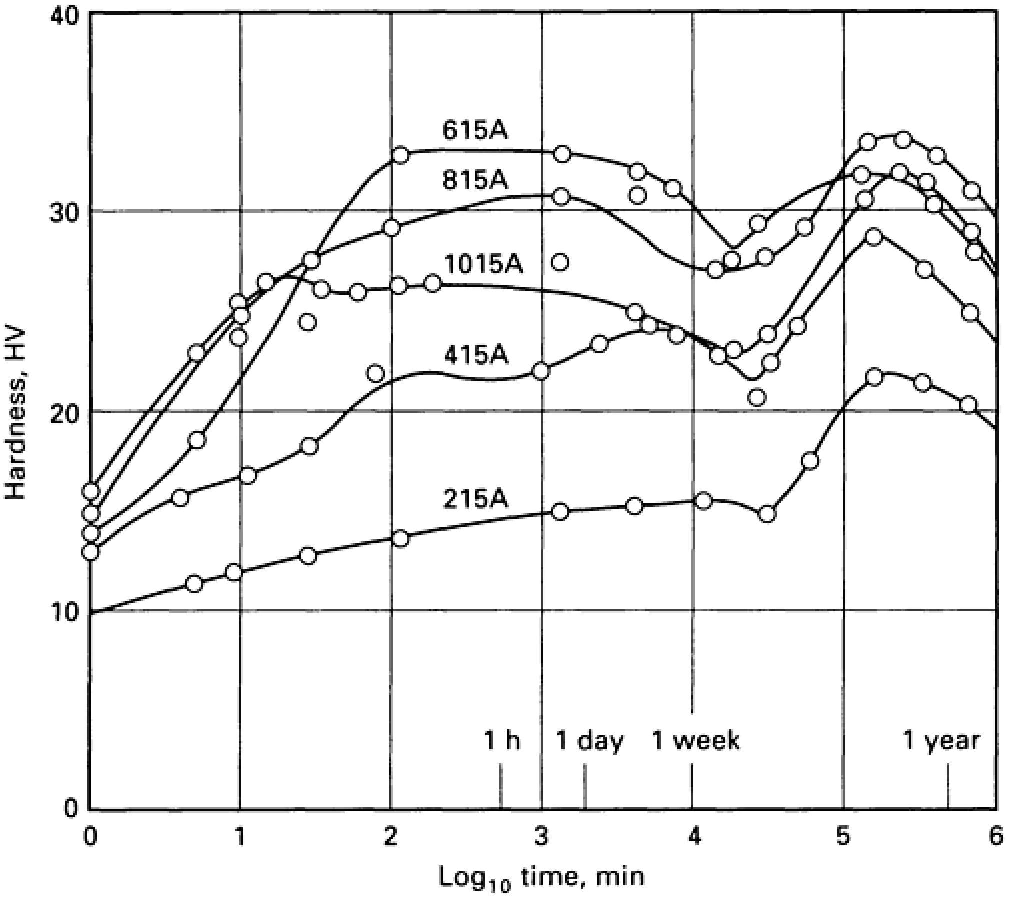

Fig. 3 Age hardening of lead-antimony-arsenic alloys, solidified and water quenched

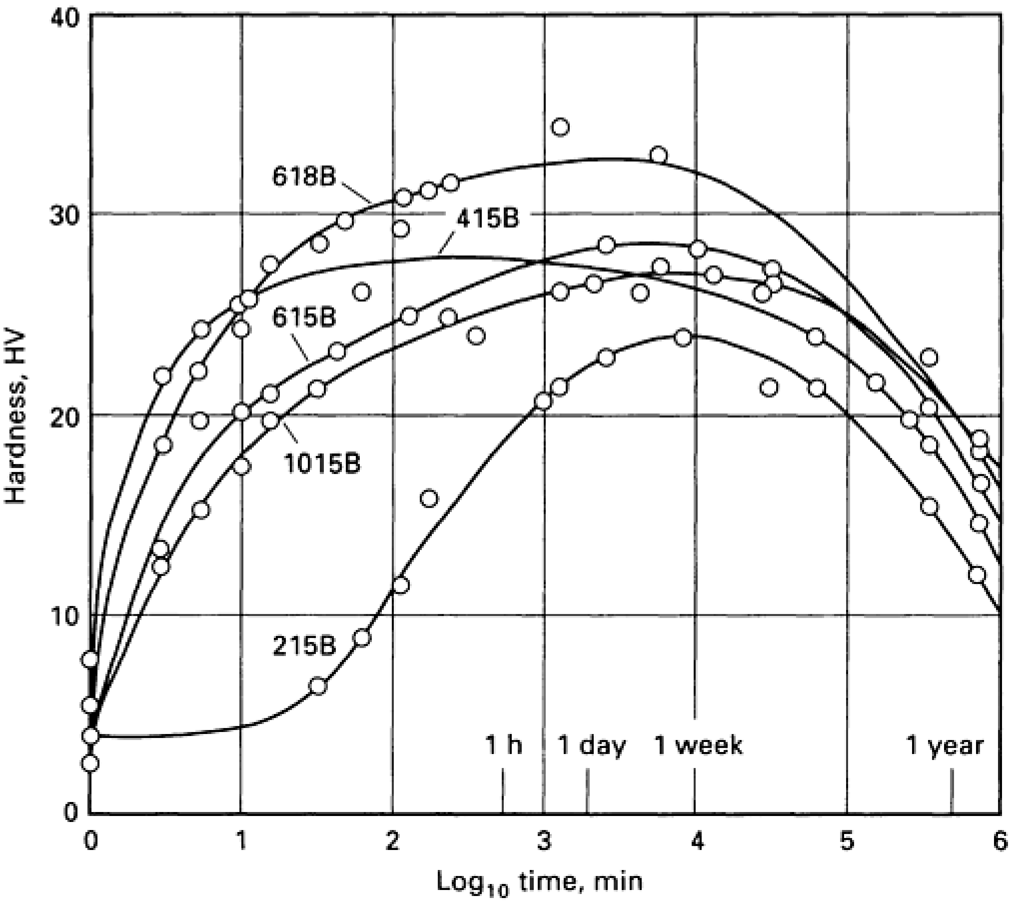

Fig. 4 Age hardening of lead-antimony-arsenic alloys, solution treated 4 h at 250 °C (480 °F) and water quenched

Hardness Stability. For any given alloy, both heat treatments result in somewhat comparable hardnesses after 1 min and after 2 years, as indicated in Fig. 1, 2, 3, and 4. For most of the two-year period, the solution-treated specimens were harder than the quench-cast specimens. Other investigations have also shown that alloys cooled slowly after casting are always softer than quenched alloys. As shown in Fig. 3, the alloys with 2 and 4% Sb harden comparatively slowly, and the alloy containing 6% Sb appears to undergo optimum hardening.

Application. Because of the detrimental effect of antimony on charge retention, the effort to reduce antimony contents of the positive plates in lead-acid storage batteries has led to the trend of replacing eutectic alloys with a Pb-6Sb-0.15As alloy. Battery grids made of this arsenical alloy will age harden slowly after casting and air cooling. However, storing grids for several days constitutes unproductive use of floor space and results in undesirable interruptions in manufacturing sequences.

Although large-scale solution treatment of battery grids might be difficult to justify economically or to achieve without some distortion, quenching of grids cast from arsenical lead-antimony alloys offers an attractive alternative method of effecting improvements in strength. The suitability of quench-cast grids can be assessed by comparing the values given in Fig. 3 with the hardness level that battery grids require in order to withstand industrial handling (about 18 HV, the hardness of the eutectic alloy). The alloy containing 2% Sb clearly does not respond sufficiently to be considered as a possible alternative. The 4% Sb alloy, however, attains a hardness of 18 HV after 30 min, and the alloys that contain 6, 8, and 10% Sb could be handled almost immediately. Furthermore, the values given in Fig. 3 for hardness after two years are superior in all instances to those for air-cooled alloys of similar composition. Hardness curves decline steadily after two years, and full evaluation of these alloys for use in the battery industry would require battery performance tests.

Dispersion Hardening

Another mechanism for strengthening of lead alloys involves elements that have low solubilities in solid lead, such as copper and nickel. Alloys that contain these elements can be processed so that no homogenization results; most of the strengthening that occurs is developed through dispersion hardening, with some solid-solution hardening taking place as a secondary effect. The resulting structure is more stable than those developed by other hardening processes. Dispersion strengthening also has been achieved through powder metallurgy methods in which lead oxide, alumina, or similar materials are dispersed in pure lead.

Fabrication

Although alloy selection is important, care must be taken in fabrication as well. Castings should be cooled rapidly to a temperature below that at which the structure breaks down, or a coarse structure will be obtained. Age-hardening alloys should be extruded at a temperature above the breakdown temperature, and extrusions should not be allowed to cool slowly. Rolled alloys often are processed at insufficient temperatures; when this occurs, homogenization after rolling is required if age hardening is to produce a beneficial response.

Cold Storage

Cold storage has been shown to improve the response of lead-antimony alloys to age hardening. Cooling a homogenized Pb-2Sb alloy to -10 °C (15 °F) and holding for one or two days prior to room-temperature aging results in increases in both the rate of age hardening and the maximum hardness attained. This behavior has been explained as the result of a reduction in the mobility of quenched-in free vacancies and a consequent reduction in their annihilation. The process allows the vacancies to form complexes with solute atoms, and these complexes improve the efficiency of nucleation during aging.

Service Temperatures

Service temperatures for lead alloys must be kept low to prevent overaging. Some cable-sheathing alloys, for example, have retained most of their creep resistance for up to 20 years, but exposure to elevated temperatures could have reduced this performance substantially. Even the normally stable age-hardened lead-antimony and lead-calcium alloys can be altered detrimentally by high service temperatures or excessive working.

Heat Treating of Uranium and Uranium Alloys

Revised by Gerard M. Ludtka and E.L. Bird, Materials Engineering Department, Development Division, Martin Marietta Energy Systems, Inc.

Introduction

THE MAJOR APPLICATIONS of depleted uranium (DU) and its alloys are those for which density is an important, if not an overriding, consideration (at 19.05 g/cm^3, unalloyed depleted uranium is one of the densest of all elements). Among these applications are kinetic energy penetrators for military use, aircraft and missile counter-weights, radiation shielding, gyrorotors, high energy physics calorimeters, and ballast. Dilute alloys containing 0.75 wt% Ti or 2 wt% Mo are used in production of kinetic energy penetrators (the largest single application of DU) because superior mechanical properties can be developed in these alloys, and their corrosion resistance can be improved, by heat treatment.

Although most DU was originally produced in cast form and used without heat treatment, current material requirements usually call for heat treated, wrought DU for property consistency. Ingot breakdown and primary fabrication processes, such as forging, rolling, and extruding, can be readily carried out between 550 and 640 °C (1020 and 1180 °F) or between 800 and 900 °C (1470 and 1650 °F). The 650 to 780 °C (1200 to 1435 °F) range is avoided because cracking commonly occurs at these temperatures. Secondary fabrication processes such as rolling, swaging, and straightening are commonly done between room temperature and 500 °C (930 °F). Following heat treatment, machining to final dimensions can be

carried out by most conventional cutting and grinding techniques. This article focuses on the heat treatment of uranium alloys. Additional information on processing, including heat treatment, is also provided in Volume 2 of *ASM Handbook*, formerly 10th Edition *Metals Handbook* and in the Selected References at the end of this article.

Metallurgical Characteristics of Depleted Uranium

In processing of uranium, several considerations must be addressed: hydrogen embrittlement and hydride formation; ready oxidation in air, attack by hot water; and dissolution by acids. In addition, fine particles of uranium metal are pyrophoric and can ignite spontaneously at room temperature.

The metal uranium is obtained from uranium hexafluoride (UF_6) tailings from the uranium enrichment process that provides U-235 uranium for the nuclear industry. In typical production of depleted uranium, UF_6 tailings are reduced to uranium tetrafluoride (UF_4), called "green salt," which is further reduced to derby uranium metal by a thermite-type bomb reduction with magnesium metal. Calcium metal has also been used to reduce UF_4 to derby metal. Typical derby chemical analysis ranges (in ppm) are 5 to 50 Cu, 8 to 40 Al, 30 to 150 Fe, 10 to 50 Ni, 10 to 100 Si, 1 to 10 Mg, 10 to 50 C, 15 to 40 O, 8 to 40 N, and 4 to 18 H. Minor high-vapor-pressure contaminants can be removed by volatilization during subsequent vacuum melting operations, while the other listed elemental contaminants remain. These impurities should be monitored and controlled to ensure expected metallurgical response to processing. Typical chemical and gas analyses for vacuum-induction-melted depleted uranium are shown in Table 1. In general, hardness varies directly, and ductility varies inversely, with impurity content.

Table 1 Typical chemical and gas analyses for vacuum-induction-melted DU

Element	Average analysis, ppm (by wt)
Carbon	180
N_2	15
O_2	40
Bulk H_2	2
Aluminum	25
Copper	15
Iron	85
Manganese	15
Nickel	20
Lead	4
Silicon	120

Phase Changes. Chemically and metallurgically, DU is identical with natural uranium. Transformation from the alpha phase (orthorhombic) to the beta phase (tetragonal) occurs at 662 °C (1224 °F). The beta phase is stable up to 773 °C (1423 °F), where it transforms to the high-temperature gamma phase (body-centered cubic). The latter is stable to the melting point, 1132 °C (2070 °F). The gamma phase in unalloyed DU cannot be retained to room temperature by commercial quench rates.

Phase changes in DU and its alloys are accompanied by significant changes in volume. Volumetric shrinkage from the high-temperature gamma phase to the low-temperature phase is 1.8%. Changes in linear dimensions are influenced by preferred orientation. For a random orientation, linear shrinkage is 0.6%. Because shrinkage cannot be predicted accurately, these dimensional changes make it impossible to machine (DU) to final dimensions before heat treatment. In rough machining for heat treatment, an envelope at least 0.4 to 0.5 mm (0.015 to 0.020 in.) thick should be allowed for final machining.

Grain Size and Orientation Control

The grains of cast DU or of DU worked in the gamma region are quite large, typically 2 to 3 mm (0.08 to 0.12 in.) in diameter. Large grain sizes are undesirable for material that is to be worked because they result in rough machined surfaces and variations in mechanical properties. On a macroscale, grain size can be refined considerably by multiple beta quenching. In workpieces more than 25 mm (1 in.) thick, however, refinement is limited to an outer layer of grains because the cooling rates at greater depths are too low. Generally, the rim of fine-grain material is sufficiently thick to produce a smooth surface after subsequent working.

Beta treatment is also used as a heat treatment for DU worked in the high alpha temperature range. Beta treatment consists of heating the DU into the beta range, holding for a suitable time and cooling at a rapid rate. A common temperature range is 720 to 730 °C (1330 to 1350 °F). The purpose of this heat treatment is to eliminate the preferred orientation that develops during working.

The final alpha grain size is insensitive to temperature within the beta range and to variations in holding time. Times from 1 min to 1 h at temperatures greater than 700 °C (1290 °F) have no effect on final alpha grain size. Cooling rate, however, has a significant effect. Water-quenched material has a significantly finer grain size, and the grains have scalloped edges which are indicative of the massive transformation which occurs during rapid beta quenching. Air-cooled grains have more uniform boundaries. Extremely low cooling rates, such as those obtained in a furnace-cool cycle, produce large alpha grains. Also, detrimental grain growth to as-cast grain sizes can occur in wrought DU through an extended alpha anneal.

High cooling rates such as those achieved by water quenching produce high residual stresses in beta-treated material. In thin sections, these residual stresses can produce appreciable plastic deformation in the alpha phase. This alpha phase can be recrystallized, and sometimes grain refined, by an anneal in the alpha range. Alpha annealing after beta treatment will not produce recrystallization at the center of a thick section, because the center does not cool rapidly enough for sufficient straining of the lattice to occur.

When DU is water quenched from the beta phase, high stresses develop due to the combination of (a) the radial temperature gradient and (b) volume contraction during beta-to-alpha transformation. These stresses are compressive at the surface and tensile at the center. The tensile stresses are high enough to produce failure near the centerline. Large numbers of repetitive quenches from the beta phase can produce sponginess, cracks, or holes in the center section of the workpiece.

Grain growth is extremely sensitive to orientation as well as to differences in metal purity, to prior deformation, and to heat treatments that affect the dispersions of contaminant second phase. Those contaminants that are in solution tend to delay recrystallization and often result in mixed, or incomplete, recrystallized structures. Those elements having uranium compounds that show limited solubility, thereby existing as inclusions, do not delay recrystallization appreciably.

The amount of work that exists in uranium metal prior to heat treatment has an important effect on final grain size. A 1 to 2% strain in uranium constitutes critical strain. Recrystallization of material with this amount of strain results in very large grains. Consequently, a plate prepared for forming operations is produced with 10 to 15% warm work to ensure that no areas of critical strain exist in the final wrought product. As the amount of work in the metal to be annealed is increased, the temperature needed for uniform recrystallization is lowered. For most formed parts made from relatively pure material, recrystallization will not occur below 400 °C (750 °F) with annealing times of up to 10 h.

Cold Working

Alpha uranium is slightly softer than steel and is considered to be malleable and ductile. Alpha uranium is readily worked at room temperature; however, directionality and texture persist because of a pronounced anisotropy. Aside from the complication of directionality, the tensile strength of uranium can be greatly enhanced by cold working, as shown in Table 2; hardness also can be increased significantly, as shown in Table 3.

Table 2 Typical mechanical properties of DU as functions of amount of cold work

Annealing

Annealing of cold-worked DU is similar to that in other metals. The first stage is recovery, in which there is a slight decrease in hardness, a small decrease in electrical resistivity and a pronounced sharpening of x-ray line shape. Recovery is followed by recrystallization. The variation of recrystallization temperature as a function of cold work is shown in Fig. 1 for an annealing time of $1\frac{1}{2}$ h. Recrystallization begins at 400 °C (750 °F) and is complete at 450 °C (840 °F) in material cold worked 90 to 94%. Light cold working (about 4%) causes recrystallization to begin at 525 °C (975 °F), but recrystallization is not complete after $1\frac{1}{2}$ h at 600 °C (1110 °F).

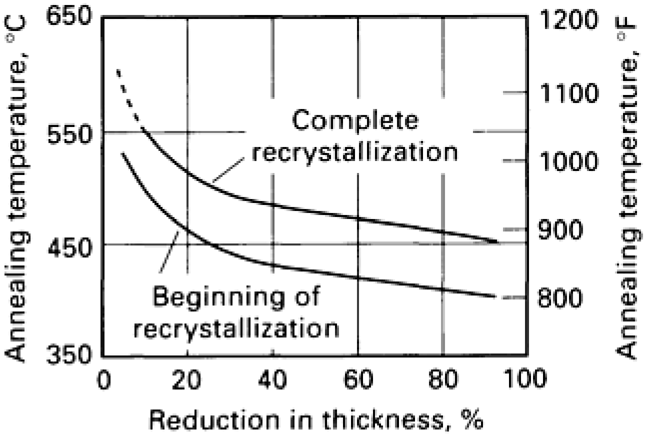

Fig. 1 Recrystallization temperature as a function of cold work for rolled depleted uranium of moderate purity. Annealing time, $1\frac{1}{2}$ h. Source: Ref 1

The grain size of cold-worked and annealed DU depends upon a variety of factors: annealing time and temperature; amount and homogeneity of the cold work strain; cold working temperature; and volume, size, and dispersion of inclusions. Cold or warm working of DU often results in a banded or duplex structure; this persists as a duplex grain size after recrystallization. The average grain size for material rolled to 50% reduction at 300 °C (570 °F) is illustrated in Fig. 2. This shows the effect of annealing temperature (annealing time, 1 h) on materials of various purities. Grain size is about 0.01 to 0.015 mm (0.0004 to 0.0006 in.) for impure uranium and as large as 0.04 mm (0.0015 in.) for high-purity metal.

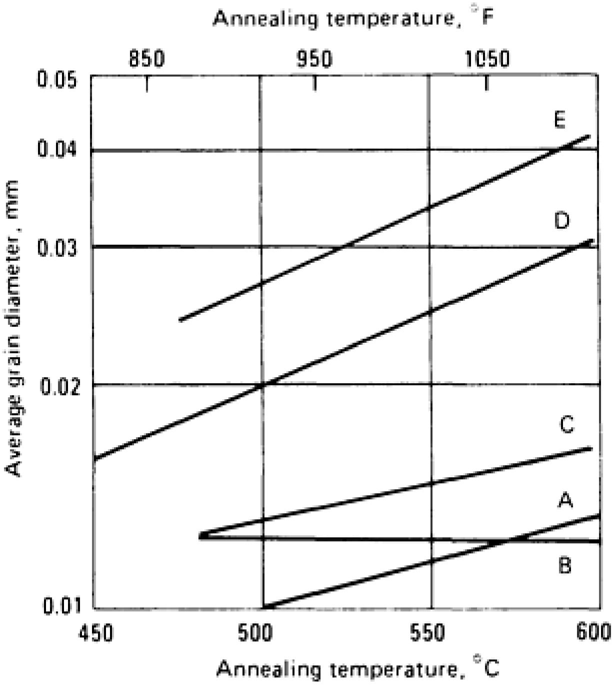

Fig. 2 Average grain size of depleted uranium as a function of annealing temperature. 1-h anneals after 50% reduction by rolling at 300 °C (570 °F). A and B are impure metal; C, D, and E are high-purity uranium in decreasing order of submicroscopic inclusion content. Source: Ref 2

Table 4 presents typical mechanical properties of uranium in various conditions. These data are not precise values and are intended for use only as guidelines for selection of heat treatments.

The following heat treating procedure can be followed to produce fine-grain material. It is best to start with a relatively pure material that has very small amounts of inclusion-producing impurities. Following a hot breakdown of the rolling ingot at 630 °C (1165 °F), rolling operations are performed at 300 to 400 °C (570 to 750 °F). After 40 to 60% warm work, the material is given a short recrystallization anneal (about 30 min per inch of thickness) at 630 °C (1165 °F). The rolling stock is cooled from the annealing temperature to below 400 °C (750 °F) and given further warm work. This process is repeated as often as final stock thickness will allow.

If the rolled stock is to be used in subsequent forming operations, the final rolling procedure should leave 15 to 20% warm work in the plate. Forming operations should be carried out warm at temperatures not exceeding 375 °C (705 °F). A final anneal at 630 °C (1165 °F) for 30 min per inch of thickness (minimum, 6 to 8 min) will produce parts with a grain size of ASTM 6 to 10, depending on the amount of warm rolling possible. Intermediate anneals at temperatures below the suggested 630 °C (1165 °F) will help develop the finer grain size. Test specimens will be required to establish the times necessary at these lower temperatures to effect complete recrystallization.

Alpha recrystallization annealing will not remove the anisotropy of the crystal structure produced by the rolling and forming processes. The stock for most forming operations is produced by "square rolling," or by giving the rolled plate essentially equal reductions in the longitudinal and transverse directions. This process produces a plate with relatively uniform properties in the plane of the plate. Equal reductions taken at 45° to the standard longitudinal and transverse directions will produce even more uniform forming stock.

Cast Uranium. The grain size of cast uranium is difficult to define because the large cast grains all have well-organized substructures (see Fig. 3). The cast microstructure and mechanical properties can be improved by beta heat treating (see Fig. 4). In this process, the casting is heated to about 740 °C (1365 °F), water quenched, and then given an alpha anneal. Grain refining occurs because of the presence of small levels of uranium-iron and uranium-silicon compounds. These compounds are put into solution by the 740 °C (1365 °F) (or higher) beta heat treatment, kept in solution by the water quench, and then precipitated by the alpha anneal. If the alpha-anneal temperature is low, the precipitation of the compounds is fine and well dispersed.

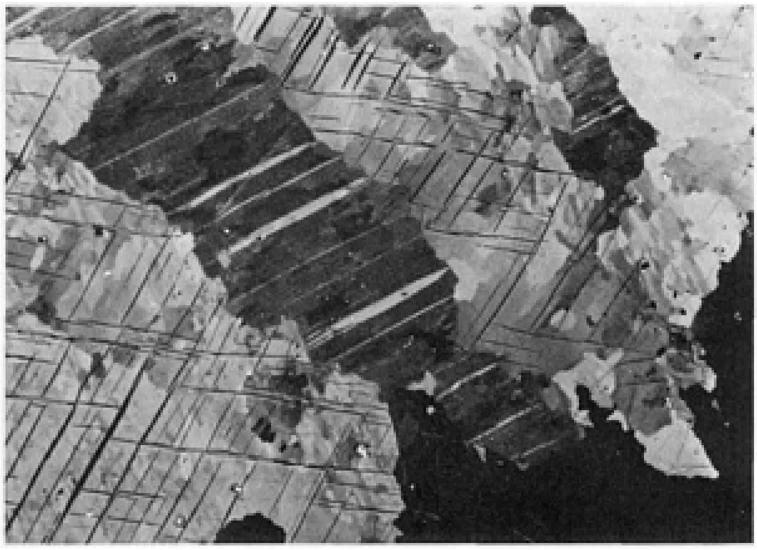

Fig. 3 Typical grain structure of cast depleted uranium

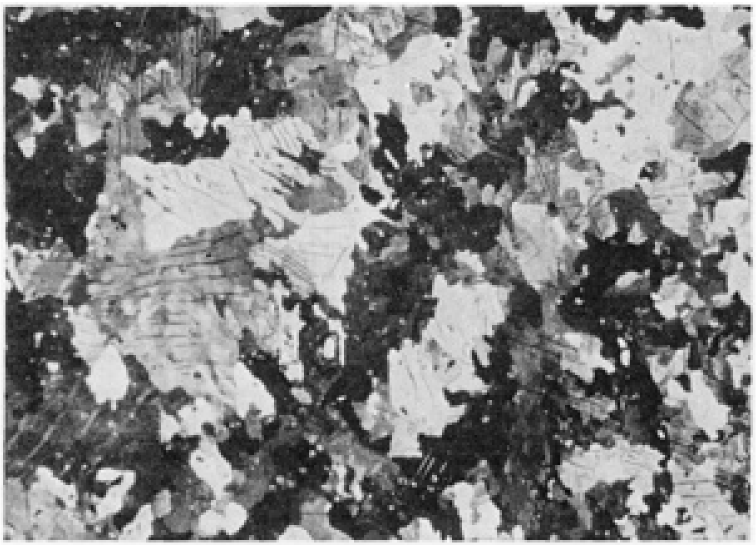

Fig. 4 Microstructure of cast depleted uranium refined by beta quenching

Figure 5(a) shows fine U_3Si precipitates in a U-400ppm Si-200ppm Fe alloy after a beta quench and 625 °C (1160 °F) anneal. Finer precipitation is evident in a U-200ppm Fe alloy annealed at 600 °C (1110 °F) as exhibited in Fig. 5(b). After this fine precipitate dispersion is achieved, a second beta quench can be more effective as a grain refining step. Two beta quenches and two alpha annealing cycles will produce the desired grain structure in stock as thick as 32 mm, or 1.25 in. (see Fig. 4).

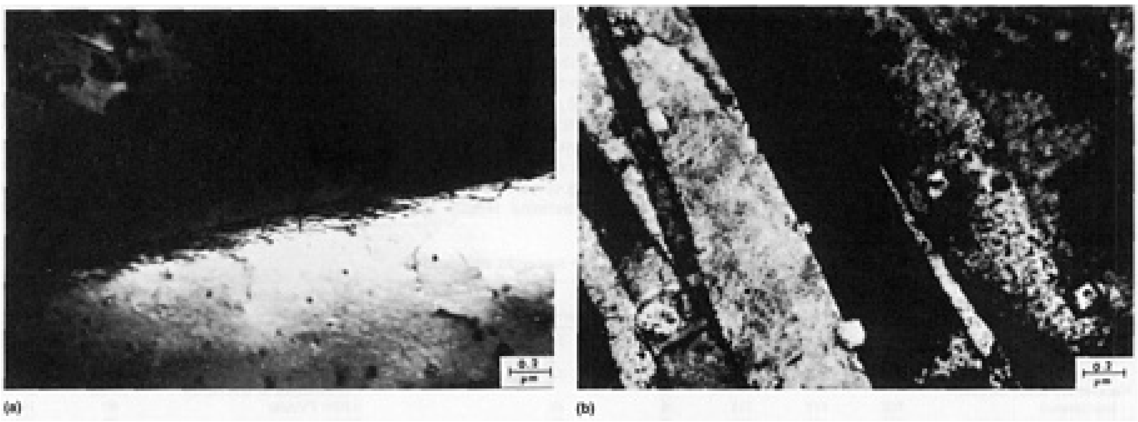

Fig. 5 Micrographs showing precipitates in dilute-impurity uranium alloys after beta solution treatment of 730 °C (1345 °F) for 30 min followed by water quenching and an aging treatment. (a) U_3Si precipitates in a U-400 ppm Si-200 ppm iron alloy after a beta quench followed by an aging treatment of 625 °C (1160 °F) with furnace cool. (b) Fine precipitation in a U-200 ppm iron alloy after a beta quench followed by an aging treatment of 600 °C (1110 °F) for 20 h with a furnace cool

The specific details of the recommended beta heat treatment--such as temperature, time, quenching procedure, and furnace conditions--are dictated by the final metallurgical condition desired. When beta heat treating is followed by water quenching, the uranium lattice undergoes heavy strain as a result of the beta-to-alpha transformation. This transformation can occur by diffusion, massive, or martensitic mechanisms depending on the severity of quenching. At slower cooling rates, the beta-to-alpha transformation occurs by diffusion. A massive transformation mechanism has been shown to dominate at intermediate quench rates of 20 to 100 °C (35 to 180 °F/s), whereas a martensitic reaction has been observed for the most rapid quench rates in the dilute impurity alloys. In general, to relieve the residual stresses induced by beta quenching and to precipitate a fine dispersion of secondary compounds, an annealing temperature of 575 °C (1065 °F) is used. Typical tensile properties that can be developed by various heat treatments in cast and wrought uranium are shown in Tables 5 and 6, respectively.

Dilute Alloys of Depleted Uranium

Dilute alloys that are heat treated in larger quantities are DU-(0.70-0.85) wt% Ti and DU-2 wt% Mo. Both are used as cores in kinetic energy penetrators. The ability of these alloys to age harden is related to the fact that titanium and molybdenum have extended solid solubility in the high-temperature gamma phase and essentially complete insolubility in

the low-temperature alpha phase. On rapid quenching, the gamma transforms martensitically to supersaturated alpha prime. A fine dispersion of intermetallic compound develops during subsequent aging at temperatures above 300 °C (570 °F).

Figure 6 shows the microstructure of water-quenched 36 mm (1.4 in.) diam U-0.75Ti bar. The outside of the bar (Fig. 6a) has transformed completely to lenticular alpha prime. The fineness of this structure increases with increasing quench rate. The grain boundaries visible in the structure are those of the prior gamma grains. The U-0.75Ti alloy is shallow hardening, however. At the center of the bar, transformation to alpha phase plus U_2Ti starts at prior grain boundaries (Fig. 6b). Similar structures are found in 18 mm (0.7 in.) diam bar oil quenched from the gamma phase. Aging to peak hardness produces no detectable change in structure.

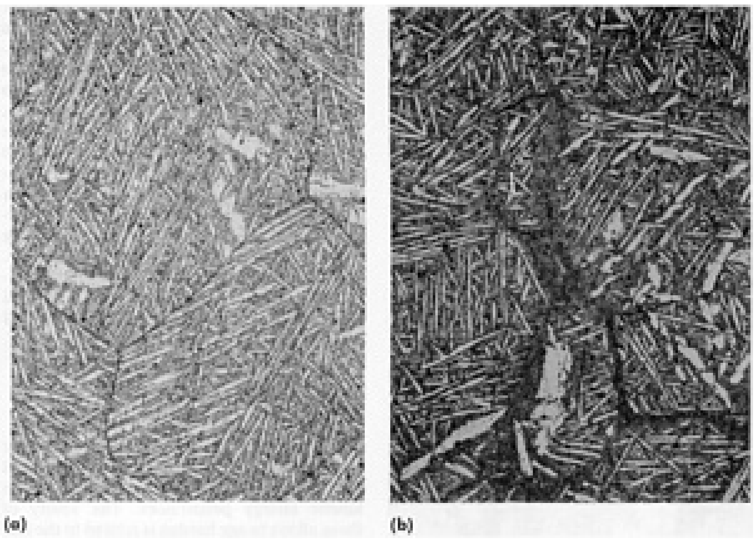

Fig. 6 Microstructure of solution treated and quenched U-0.75Ti. Bar 36 mm (1.4 in.) in diameter and quenched into water at 455 mm/min (18 in./min). Chrome-acetic electroetch. 100×. (a) Edge. (b) Center

Solution Treating and Aging. Heat treating for improved hardness and mechanical properties in dilute DU alloys consists of solution treating in the gamma-phase temperature range of 800 to 850 °C (1470 to 1560 °F), quenching to room temperature, and aging in the alpha temperature range. Solution heat treatment is usually done in vacuum or an argon atmosphere for oxidation control and hydrogen outgassing. Alternatively, interrupted quenching in a molten metal or salt bath held at the appropriate temperature can be used.

A completely gamma phase microstructure can be produced in a very short time, 2 to 5 min, depending on the thickness. Longer solution heat treatment times of 4 to 8 h are generally used for thicker components and for hydrogen outgassing. Excessive soak times lead to unfavorable, large gamma grain sizes which influence the final martensite lathe size obtained upon water quenching.

An important consideration in the selection of conditions for gamma solution treatment is the hydrogen level required in the final product. Although hydrogen is detrimental to ductility in the U-0.75Ti alloy, acceptable ductility with occasional low values can be achieved with H_2 levels below nominally 1 ppm. However, higher and more consistent properties (less scatter) are best obtained when H_2 levels are maintained at 0.1 ppm or less.

Erratic ductile behavior in U-0.8Ti can be offset by controlling the effects of hydrogen by reducing the internal hydrogen content from 0.36 ppm to 0.02 ppm H_2 and testing in dried air containing less than 10% relative humidity. A recent study (Fig. 7) showed a 50% improvement in ductility with no loss in strength. Scanning electron microscopic evaluation of the fractured tensile specimens revealed a correlation of premature failures originating at inclusion clusters, identified as titanium carbides and/or uranium oxides. These results indicate that as the hydrogen content increases, there is a greater likelihood of premature or erratic fracture at an inclusion cluster or other defect. As expected, large defects or inclusion clusters cause a significant loss in ductility regardless of the hydrogen level. Unalloyed uranium and uranium alloys are sensitive to hydrogen and for maximum material properties require extensive outgassing. The literature should be consulted before selecting conditions for these alloys.

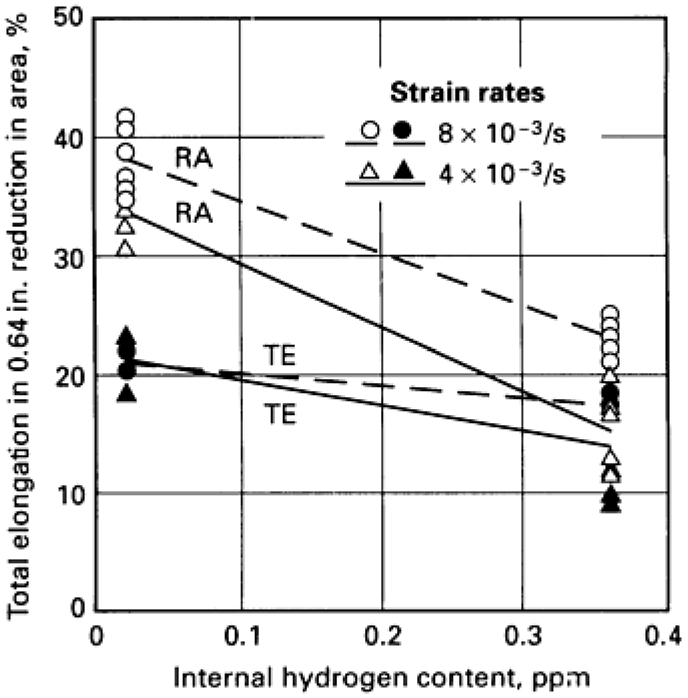

Fig. 7 Effect of hydrogen content and strain rate on the ductility of a conventional tensile test for the U-0.8Ti alloy. RA, reduction in rate; TE, total elongation in 16.3 mm gage length

Quenching. Table 7 gives the rates at which DU-0.75Ti cools when quenched in various media. The test slugs used for measuring these rates were 22 mm (0.875 in.) in diameter by 21 mm (0.845 in.) long. Cooling rates for other DU alloys should be similar. Because DU-Ti alloys are quench rate sensitive (shallow hardening), higher quench rates are needed to achieve uniform hardening response in large diameter bars or thicker plates.

Table 7 Cooling rates for DU-0.75Ti in various quench media

Media	Quench rate	
	°C/s	°F/s
Flowing argon	3.8	6.8
Conventional or soluble oil	38-40	68-72
0.05% PVA[a]	80	145
Water	98	175

(a) Polyvinyl alcohol

Effect of Quench Rate on Microstructures. Figure 8 shows the effect of quench rate on the microstructures developed during quenching. A truly 100% martensitic microstructure can be obtained only in very thin, rapidly quenched samples (<3 mm) as shown in Fig. 8(a). Even after excessive etching (as evidenced by pitting at the grain boundaries), the α' martensite is not resolvable in bright field optical micrographs but is easily detected under polarized light conditions. As the quench rate is reduced (or the quenching blank becomes more massive), some equilibrium α+ δ is formed preferentially at prior γ grain boundaries and along martensite lathe interfaces.

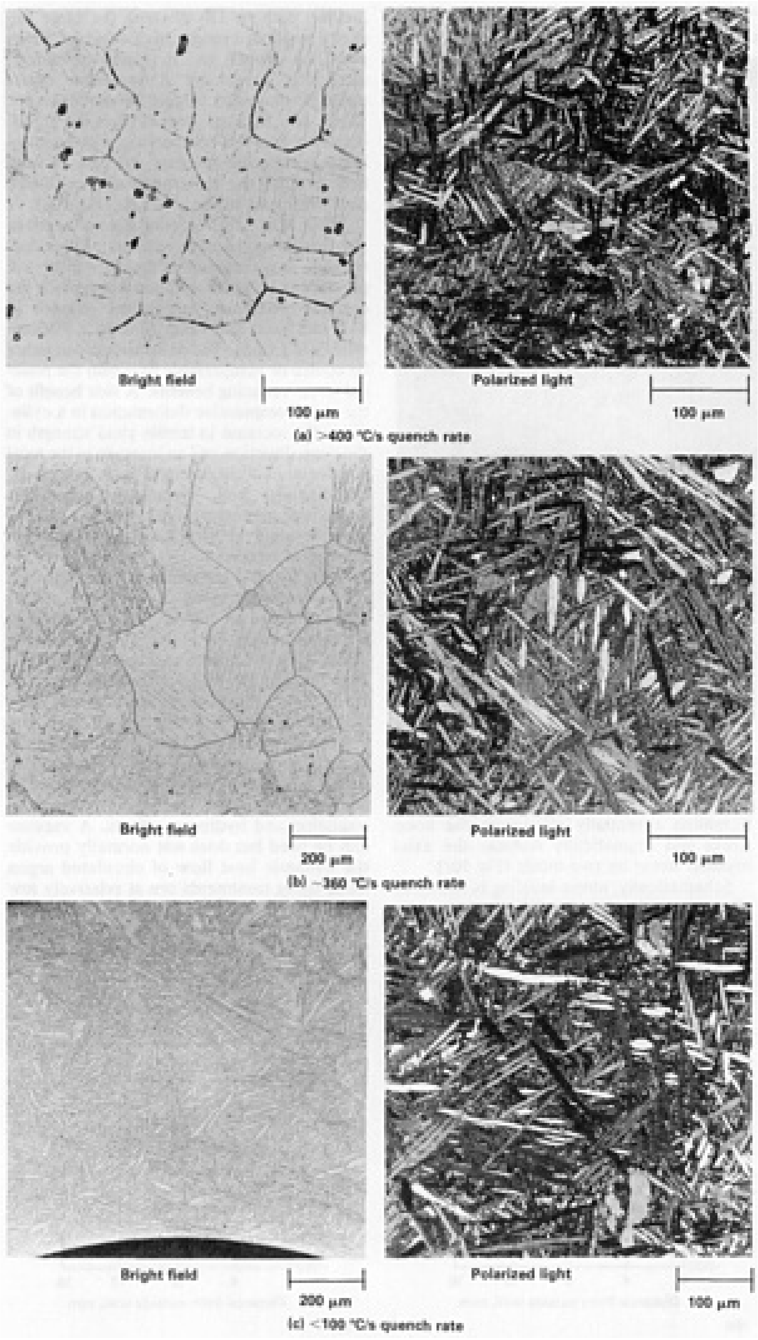

Fig. 8 Effect of quench rate on the microstructure of a U-0.8Ti alloy as seen in bright field and polarized light optical micrographs. (a) 100% α' martensite microstructure for a quench rate >400 °C/s (> 720 °F/s). (b) Microstructure developed at a cooling rate of ~360 °C/s (~650 °F/s) with <100% α'. (c) Approximately 90% α ' martensite developed at a <100 °C/s (<180 °F/s) quench rate

Figure 8(c) represents typical acceptable microstructures in a satisfactorily quenched U-0.8Ti alloy sample. The martensite lathes are visible in bright field due to the interface decoration by the equilibrium α+ δ. Despite the rapid phase decomposition upon quenching, acceptable properties can be achieved in aged U-0.8Ti alloy components with up to 50%

of the α + δ transformation products within the interior of the test specimens. On the other hand, the U-6Nb alloy is not a quench rate sensitive alloy. The α" martensite microstructure and desirable properties can be obtained after a gamma solution heat treatment even at cooling rates as slow as 10 °C/s (20 °F/s).

Void Formation. Small-diameter bars and plates can be plunge quenched, but larger diameter bars (greater than 19 mm, or 0.75 in.) develop centerline voids if plunge quenched. These voids pose a particularly serious problem. Once they are formed, there is no easy way to heal them. Void formation is related to the stresses caused by the large volume change associated with the gamma-to-alpha prime transformation and high radial thermal gradients. Centerline voids can be minimized by end quenching--that is, by lowering the bars, end on, at a controlled rate, into the quench media. Bars 36 mm (1.4 in.) in diameter have acceptable levels of centerline voids when quenched in this way, 18 at a time, into circulating water at 455 mm/min (18 in./min). The number and size of centerline voids, as detected by ultrasonic techniques, are substantially lower in bars end quenched at 255 mm/min (10 in./ min). A typical quench crack in the U-0.8Ti alloy that occurred during a sluggish quenching operation is shown in Fig. 9. Note the lack of α' martensite platelets along the surface where the crack originated. The aging response of the more slowly quenched bars is identical with those quenched at 455 mm/min (18 in./min).

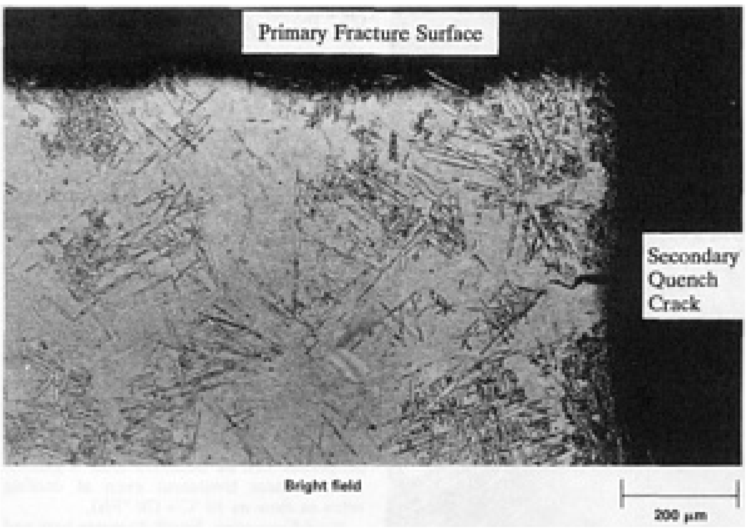

Fig. 9 A poorly transformed microstructure developed by a sluggish quench can result in a quench crack for the U-0.8Ti alloy. Acicular needles are the desired, α' martensite microstructure while the grayish regions are the undesirable, equilibrium α+ δ microstructure.

Quenching-Induced Residual Stresses and Stress Leveling. Quenching high-strength uranium alloys results in extremely high residual stresses which approach, and in some instances exceed, the yield strength of the base material. The large thermal gradients during quenching coupled with the significant difference in yield strength between the parent (γ) and product phases (either α ' or α + δ), and the phase transformation related volume contractions, induce these large residual stresses. The former are responsible for approximately 80 to 90% of the residual stresses while the latter contribute only between 10 to 20% of the quenched-in residual stresses. These latent residual stresses can be detrimental in terms of delayed fracture through stress corrosion or by significant distortion during subsequent machining operations. At times, elaborate machining procedures must be followed to obtain a final part which will meet drawing tolerances.

An example of the residual stresses obtained in a U-0.8Ti alloy cylinder after immersion water quenching is shown in Fig. 10(a). Essentially, a biaxial stress state is obtained with very high surface compressive and interior tensile residual stresses being reached. Several approaches have been used to reduce these stresses prior to final machining operations. These include thermal stress relief by aging and stress leveling through plastic deformation. Figure 10(b) shows that a typical aging heat treatment (385 °C, or 725 °F, for 4 h + water quench) after water quenching can reduce residual stresses by approximately one-third. On the other hand, stress leveling by imparting 1.5% permanent, plastic axial deformation essentially eliminates the hoop stress and dramatically reduces the axial residual stress by two-thirds (Fig. 10c).

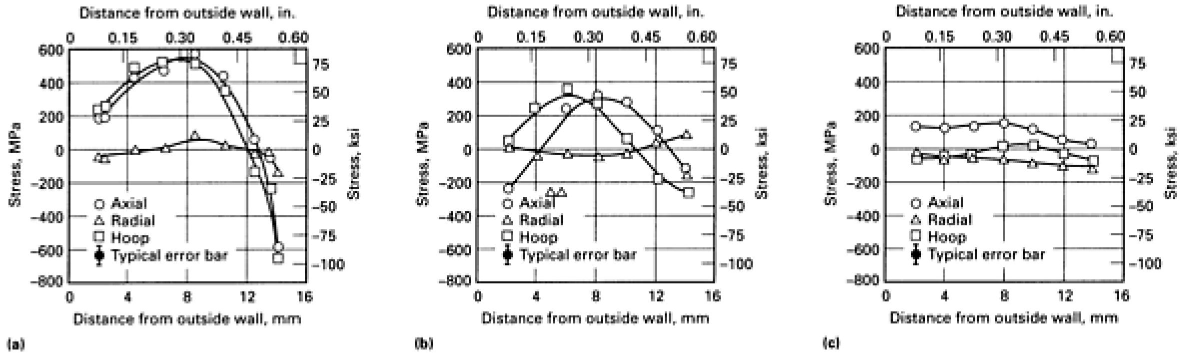

Fig. 10 Residual stresses measured by a neutron diffraction technique in a U-0.8Ti alloy cylinder. (a) After a gamma solution heat treatment and water immersion quench, a biaxial stress state is observed with very large surface compressive and interior tensile residual stresses. (b) Aging after a gamma solution heat treatment and water quench provides only a moderate reduction in the residual stresses from the original quenched values. (c) Stress leveling with 1.5% permanent, axial compressive deformation significantly reduces the residual stresses in a quenched U-0.8Ti alloy cylinder. Source: Ref 3

Schematically, stress leveling is shown in Fig. 11 for a compressive deformation cycle. Upon compressive loading, the very high tensile residual stress point 1A follows the loading path to 1B whereas the large (already yielded) compressive residual stress point 2A moves to 2B. Upon unloading, after this permanent deformation cycle, point 1B moves to 1C and 2B moves to 2C. These new residual stress values are significantly reduced in comparison with the original quenched-in residual stresses as verified through the experimentally measured data presented in the example (Fig. 10c).

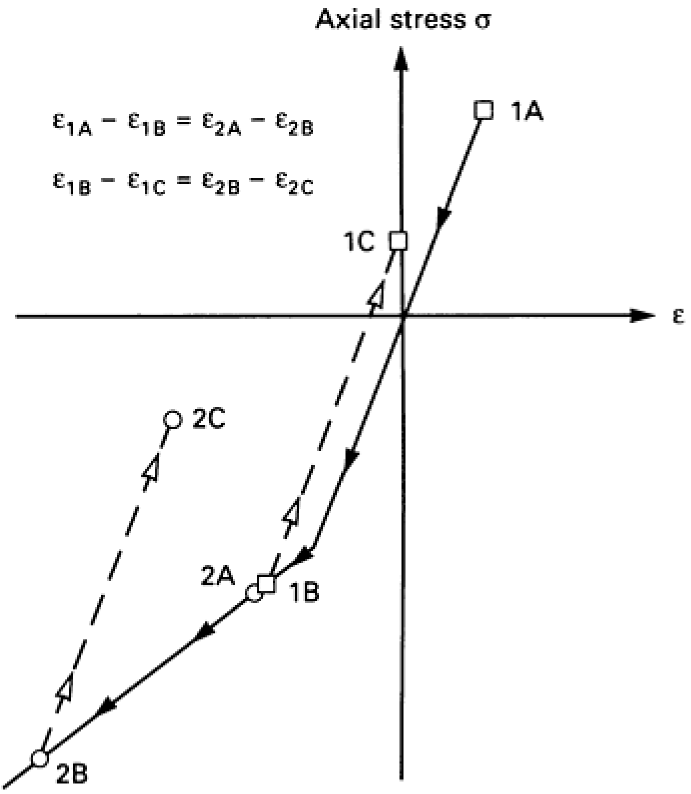

Fig. 11 Schematic of the principles of stress leveling method of residual stress reduction

Aging after stress leveling did not result in any further appreciable reduction in residual stresses. A general rule of thumb is that ~2% permanent, axial deformation will provide the optimum reduction in residual stresses in both the axial and hoop (due to a Poisson effect) directions. The deformation can either be tensile or compressive to obtain the residual stress reducing benefits. A side benefit of the axial compressive deformation in a cylinder is the increase in tensile yield strength in the hoop direction and an increase in the axial compressive yield strength with essentially no ductility loss. Geometric constraints (specimen geometry) limit the use of the stress leveling method of reducing quenched-in residual stresses.

Aging Results. Hardness and strength levels achieved on aging of dilute DU alloys are illustrated in Fig. 12, 13, and 14. The hardness curves for U-0.75Ti apply equally well to oil-quenched and water-quenched material (Fig. 12). The scatter band is caused by nominal differences in titanium and trace element contents of the alloys; iron and copper, even at low levels, contribute to the hardening response. Silicon is reported to retard hardening. Aging is usually done in an inert atmosphere like argon to minimize oxidation and hydrogen effects. A vacuum can be used but does not normally provide the dynamic heat flow of circulated argon since aging treatments are at relatively low temperatures where thermal radiation (α T^4-dependence) is not as effective for heat transfer as conduction and convection.

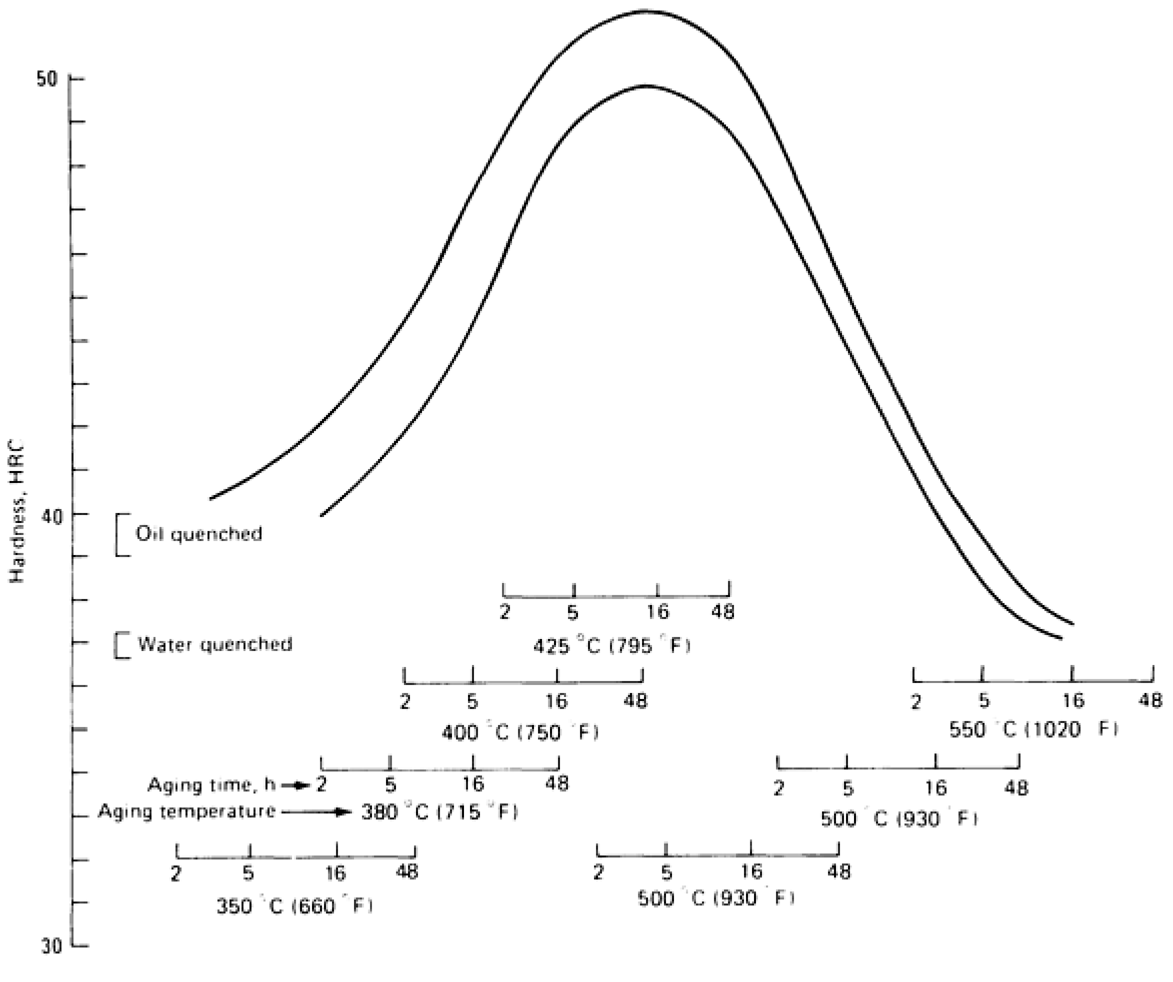

Fig. 12 Effects of aging time and temperature on hardness of U-0.75Ti

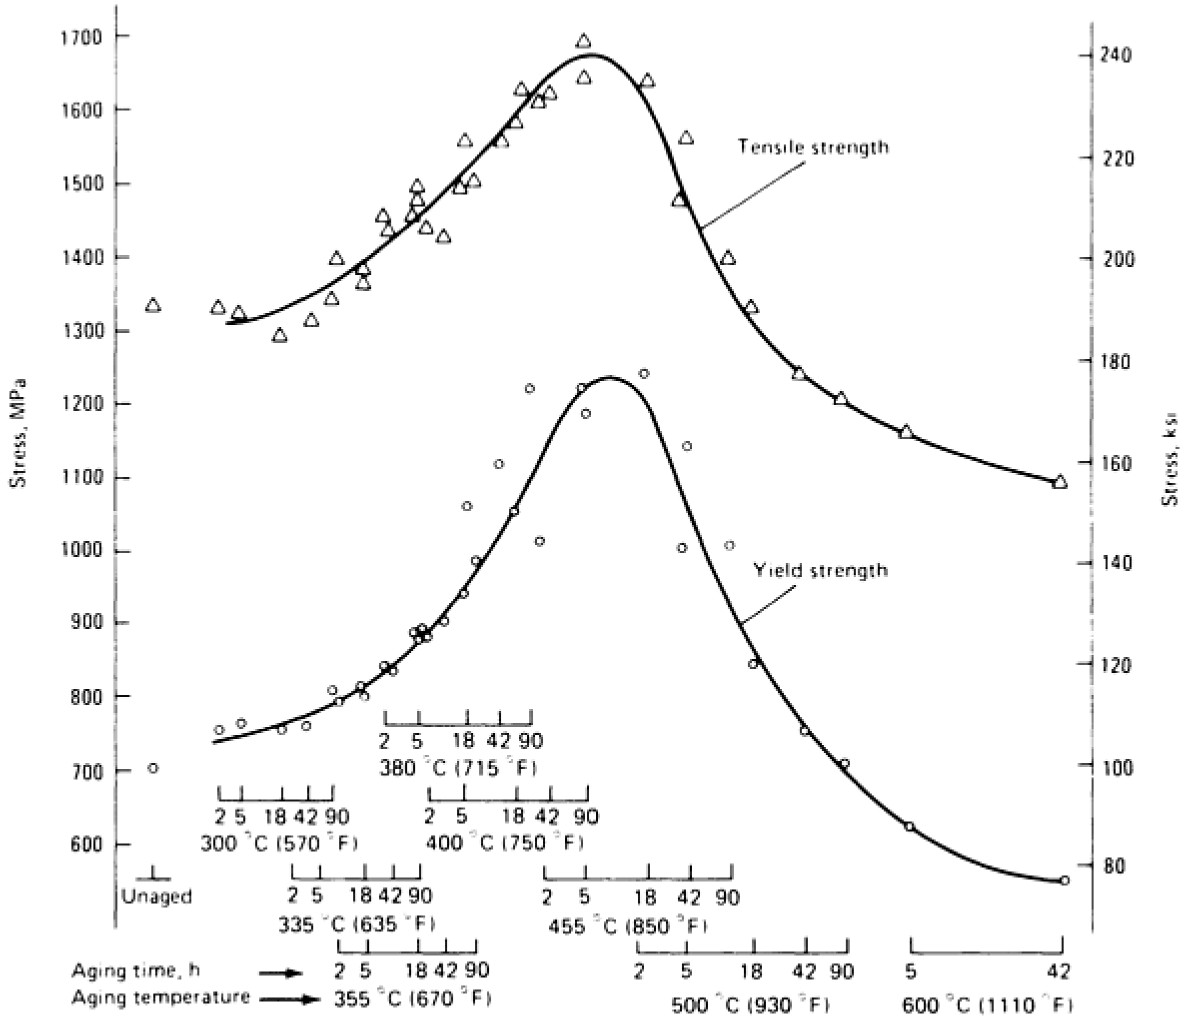

Fig. 13 Effects of aging time and temperature on tensile and yield strengths of U-0.75Ti. Source: Ref 4

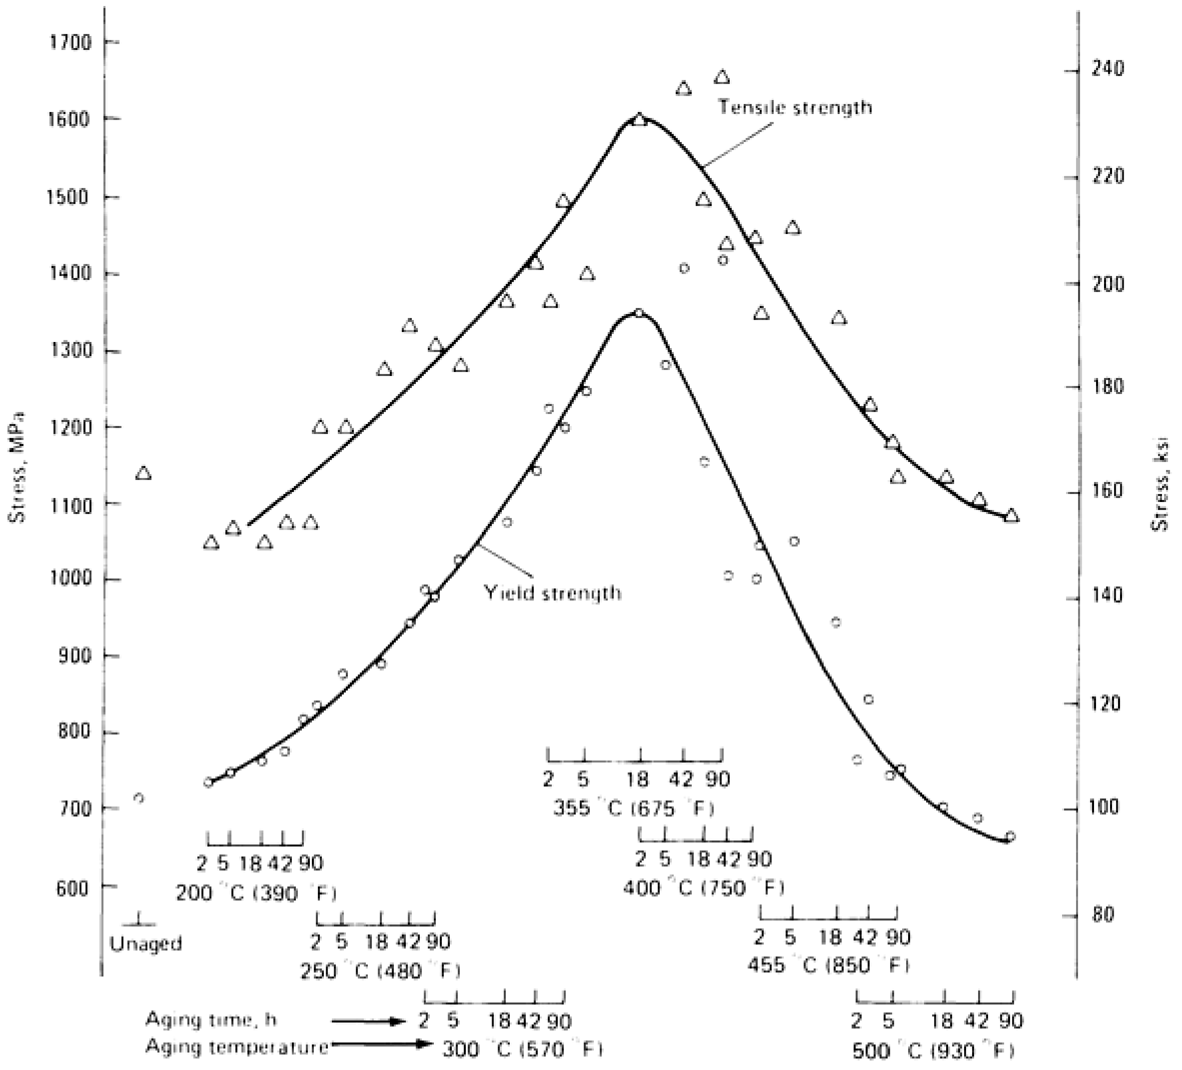

Fig. 14 Effects of aging time and temperature on tensile and yield strengths of U-2.0Mo

The heat treater has a wide selection of time-temperature options to achieve specified combinations of hardness and strength. For example, U-0.75Ti can be hardened to 45 HRC by any of the following treatments: 16 h at 380 °C (720 °F); 5 h at 400 °C (750 °F); or $1\frac{3}{4}$ h at 420 °C (790 °F). For production runs, conditions are selected to optimize equipment utilization.

Uranium alloys can differ significantly in their aging response as shown in Fig. 15. Whereas the U-2Mo alloy develops better strength/ductility combinations in the overaged condition, the U-0.8Ti alloy must be used in the underaged condition since the overaged condition exhibits poor ductility. A semicontinuous film of brittle intermetallic (U_2Ti) forms along the prior α' martensite plate boundaries during overaging of the U-0.8Ti alloy. In contrast for the U-2Mo alloy, the banded α' martensite plate boundaries do not act as preferential sites for the brittle intermetallic during overaging and so higher ductility is achievable in overaged microstructures.

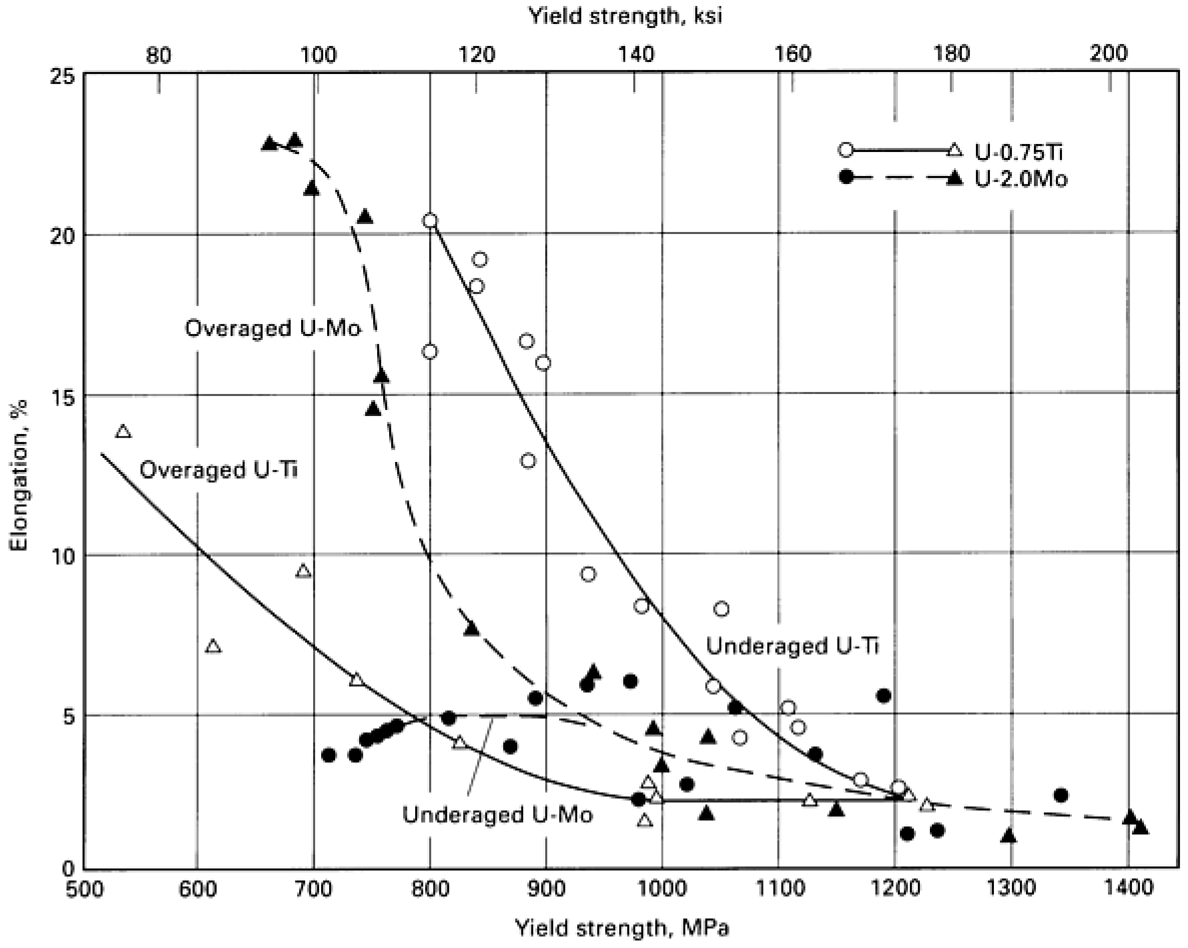

Fig. 15 A comparison between the aging responses of the U-2Mo and U-0.75Ti alloys

A general comment on the heat treatment of uranium alloys is that the elastic moduli (tensile and shear) can be varied significantly (over 100%) through heat treatment. This fact has been used as the basis for a quality control method through measurement of elastic ultrasonic wave response to verify heat treatment. This ability to vary modulus is opposite in behavior to conventional ferrous alloys which yield the same moduli independent of heat treatment.

Mechanical Testing. External hydrogen can lead to premature failures in U-0.8Ti. Ideally, the test atmosphere should be one with low relative humidity such as dried air, vacuum, or immersed in a suitable oil. Strain rate also plays a role in determining mechanical properties, especially ductility. Faster strain rates tend to improve reduction-in-area values significantly (Fig. 7). Fracture morphologies change from a mixed mode of quasi-cleavage and microvoid coalescence to one of predominantly dimpled rupture.

Metastable High Alloys

Heat treatment of DU alloys with 4.0 wt% or more molybdenum or equivalent is similar to that for dilute alloys. The treatment starts with a gamma-phase solution treatment of 1 h at about 800 °C (1470 °F). This is followed by either quenching to room temperature followed by aging in the alpha region or quenching directly to the aging temperature and holding to achieve the desired properties. For higher ductilities, it may be necessary to cold work the U-6 wt% Nb alloy prior to heat treatment. Swaging of rods at room temperature prior to heat treatment resulted in a slightly smaller grain size along with a 20% improvement in yield strength. Special care must be taken in heat treating large sections. Cracking has occurred in billets of U-6 wt% Nb 200 mm (8 in.) in diameter (or larger) that were water quenched from 800 °C (1470 °F).

Processing and Equipment

Generally, three basic furnace designs are used for heating or heat treating of unalloyed uranium: molten baths, inert-atmosphere furnaces, and vacuum furnaces. The type of furnace chosen depends primarily on desired final properties and material quality.

Uranium has been heated in molten lead for 50 h at 350 °C (660 °F) with no appreciable reaction. Longer periods and/or temperatures of 800 to 1000 °C (1470 to 1830 °F), however, have caused uranium to be completely penetrated. Molten salts are the most common heating media used in industry for preheating uranium prior to fabrication operations and for final heat treatment. Table 8 shows corrosion results for six heat-treating mixtures of salts. The main disadvantage of molten salt baths is the potential for hydrogen contamination. Consequently, any planned use of molten salt baths for heating of uranium should include a design for removing the hydrogen from the bath, such as sparging the bath with CO_2 gas. Hydrogen, which is particularly deleterious to uranium, drastically reduces its tensile elongation, as shown in Fig. 16.

Table 8 Corrosion of uranium in molten salts at 595 °C (1100 °F)

Salt mixture	Time, h	Observed attack
$44Na_2CO_3$-$30K_2CO_3$-$26Li_2CO_3$	$\frac{1}{2}$-2	No corrosion
	4	Surface pitting
$74K_2CO_3$-$26Li_2CO_3$	$\frac{1}{2}$-2	No corrosion
	4	Pitted
$47Na_2CO_3$-$32K_2CO_3$-$21Li_2CO_3$	$\frac{1}{2}$-2	No corrosion
	2	Pits beginning
	4	Badly pitted
$53K_2CO_3$-$46.6Li_2CO_3$	$\frac{1}{2}$-1	No corrosion
	2	Surface pits

20NaOH-30K_2CO_3-50Na_2CO_3	$\frac{1}{2}$ -4	Surface etching
47Na_2CO_3-47K_2CO_3-6Li_2CO_3	$\frac{1}{2}$	Scaling, 0.24% weight loss
	2	Scaling, 1.0% weight loss
	4	Scaling, 1.3% weight loss

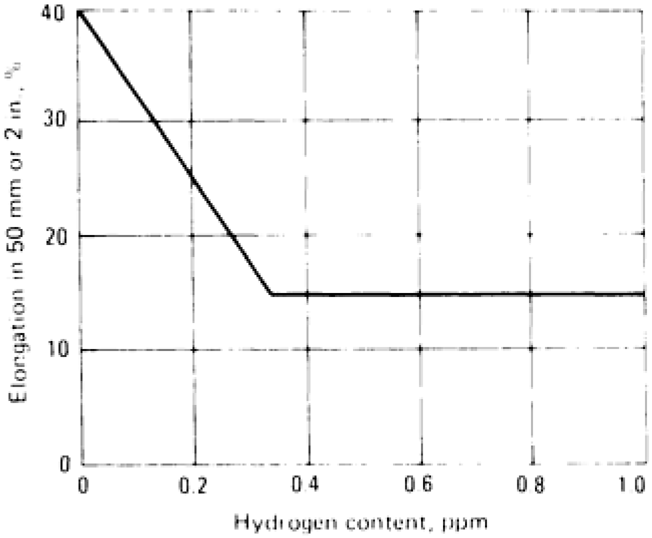

Fig. 16 Elongation versus hydrogen content for wrought depleted uranium

Furnace Atmospheres. No appreciable attack on uranium occurs in dry furnace atmosphere of helium, argon, carbon monoxide, carbon dioxide, or hydrocarbon gases at temperatures up to 500 °C (930 °F). However, relatively slight amounts of water vapor in any of these gases can cause extensive corrosion. Uranium reacts with water, in either liquid or vapor form, to produce UO_2 and hydrogen. The UO_2 spreads over the entire surface area as a black powder and, depending on the amount of exposure and purity of the metal, can result in excessive pitting and surface cratering. Thus, in heat treating of uranium in atmospheres of commercial inert gases, furnaces should be equipped with gas line dryers to dry the gas thoroughly before it is used.

Vacuum Treatment. Vacuum heat treating of uranium provides the best over-all environment for obtaining maximum tensile properties and high-quality metal surfaces. The principal advantage of vacuum-furnace heat treating is the potential for removing hydrogen from the metal.

Figure 17 shows the time required for vacuum heat treating uranium stock of different thicknesses to achieve maximum ductility. This illustration assumes an initial hydrogen concentration within the part of 2 ppm, which is typical of material processed through carbonate preheating baths, and it can be used for cast material.

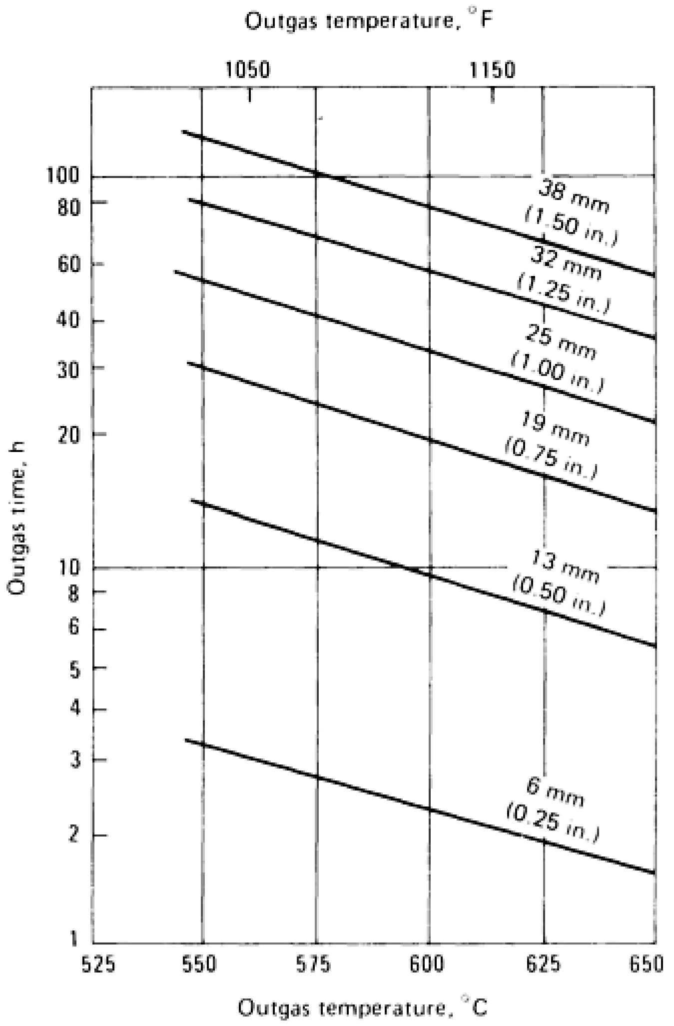

Fig. 17 Time required to achieve maximum ductility in depleted uranium plate of various thicknesses under a vacuum of 10^{-4} torr

A vacuum of 40 kPa (300 torr) limits oxidation to an acceptable level while maintaining the hydrogen at its initial level. A vacuum of 10^{-3} Pa (10^{-5} torr) is needed for significant lowering of the hydrogen level.

Cleaning. Surfaces of parts to be heat treated should be free of moisture, grease, and cutting lubricants. Heavier oxides that form on DU and its alloys can be removed by pickling for about $\frac{1}{2}$ h in a 1:1 mixture of nitric acid and water at 25 °C (75 °F). Copper, which is often used as cladding during fabrication, can also be removed with 1:1 nitric acid. U-0.8Ti should be coated with a suitable oil such as MIL-C-16173D, Grade 3 or stored in a dry environment to mitigate the deleterious effects of hydrogen.

Caution: U-Nb and U-Zr alloys can produce explosions during pickling in nitric acid. The problem can be eliminated by adding 1 to 2 vol % of hydrofluoric acid to the pickling solution.

Quenching. The oil-quench media can be contained within the vacuum chamber. Following solution treating, the furnace is backfilled with argon or helium. The work is then transferred to a position directly over the quench tank and lowered at a controlled rate into the quench media.

The high vapor pressure of water precludes incorporation of water-based quench media into the furnace. Specially designed bottom-loading furnaces have been used successfully with separate quench tanks. The sequence of events is as follows. At the end of solution treating, the quench tank is moved under the furnace. The furnace is then backfilled with

argon or helium, the power turned off, and the bottom door removed. The load is dropped rapidly to a position 50 to 75 mm (2 to 3 in.) above the water level and then is dropped at a controlled rate until all of the workpiece is submerged.

Fixtures. Neither DU nor its alloys are especially strong at gamma-solution treating temperatures. Low strength coupled with a high density places special requirements on fixturing to provide proper support and thus prevent sagging. If possible, rods and irregular-shape pieces should be placed with the long axis in a vertical position and supported every 150 mm (6 in.); spans for horizontal pieces should be limited to 75 to 100 mm (3 to 4 in.).

Figure 18 shows a fixture used for solution treating of bars 36 mm (1.4 in.) in diameter by 380 mm (15 in.) long. This basket is made of Inconel 600. Tantalum shims are often used at points of contact between DU and the basket material if the basket alloy contains a metallic element like iron, which forms a eutectic at 725 °C (1335 °F). Other common eutectics found in heat treating DU include nickel at 740 °C (1364 °F), chromium at 860 °C (1580 °F), and copper at 950 °C (1742 °F). Molten-metal attack would result in extensive local wastage of the DU and welding to the fixture.

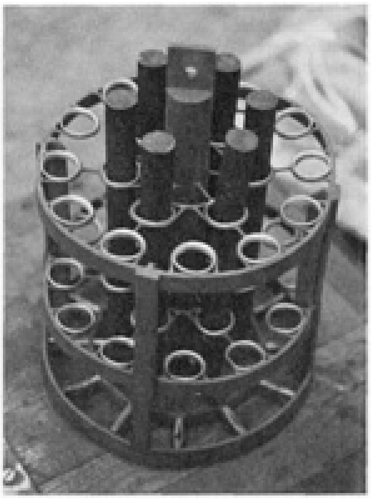

Fig. 18 Fixture for solution treating and end quenching of 18 depleted uranium bars

Salt Baths. If a salt bath is used for solution treating, the times should be kept as short as possible, not only to minimize hydrogen pickup but also to limit corrosive attack. Pieces exposed to molten chloride salts ($BaCl_2$, KCl, and NaCl eutectic) and molten carbonate salts (35% Li_2CO_3 and 65% K_2CO_3) at 730 °C (1350 °F) have lost 0.08 mm (0.003 in.) of thickness in 1 h. Such attack would be significantly more severe at 850 °C (1560 °F).

Aging treatments can be carried out in recirculating inert gas furnaces, lead baths, lead-tin baths, or molten salt baths. Because the aging reactions are temperature sensitive, the temperature should be controlled to within +5 °C (+9 °F) and preferably to within +2 °C (+4 °F). Following aging, the pieces should be either furnace cooled to 100 °C (212 °F) or water quenched. Oxidation of DU is exothermic, and the heat generated can make the reaction self-sustaining. *Caution: Rods 18 mm (0.7 in.) in diameter have reached red heat when they were not water quenched after being aged at 425 °C (795 °F) in a lead pot.*

Examples of Heat Treatment

The following procedures are examples of heat treatment used to meet certain specifications of ultimate tensile strength (UTS), yield strength (YS), and elongation. Other work related to the heat treating of specific uranium alloys is given in Ref 5, 6, 7, and 8.

Example 1: U-0.8Ti Alloy.

A U-0.8Ti alloy is to be extruded and heat treated to produce components with 1240 MPa (180 ksi) ultimate tensile strength, 895 MPa (130 ksi) yield strength at 0.85% extension, 16% total elongation with less than 0.3 ppm internal hydrogen.

- Billet is preheated in molten salt bath at 630 °C (1165 °F) and extruded
- Extruded billet is machined into blank that is solution heat treated at 800 °C (1475 °F) for 8 h in vacuum and water quenched
- Blank is aged at 385 °C (725 °F) for 4.5 h in argon and water quenched

Example 2: U-0.75Ti.

Bars of DU-0.75Ti alloy, 36 mm (1.4 in.) in diameter are to be heat treated to the following specifications: hardness, 38 to 44 HRC; minimum 0.2% yield strength, 725 MPa (105 ksi); minimum elongation, 12%; and maximum hydrogen content, 1 ppm. The procedure is to:

- Cut extruded bar stock to length
- Pickle in 1:1 nitric acid to remove copper sheath
- Rinse and air dry
- Place rods vertically in a basket
- Solution treat $2\frac{1}{2}$ h at 850 °C (1560 °F) in a vacuum of 7×10^{-3} Pa (5×10^{-5} torr), or better
- Quench into circulating water at 455 mm/ min (18 in./min)
- Air dry
- Age 16 h at 350 °C (660 °F) in an inert gas recirculating furnace

Example 3: U-6Nb Alloy.

A U-6 Nb alloy is to be formed into a hemisphere with the following mechanical properties: ultimate tensile strength, 770 MPa (112 ksi) min; yield strength at 0.2% offset, 360 to 485 MPa (52 to 70 ksi); and total elongation, 25% min.

- Billet is preheated to 800 to 850 °C (1475 to 1560 °F) and forged
- Forged billet is homogenized at 1000 °C (1830 °F) for 4 h in vacuum
- Forged billet is preheated to 850 °C (1560 °F) in molten salt bath and cross rolled into plate
- Plate is preheated in argon furnace to 850 °C (1560 °F) and formed into a hemisphere
- Hemisphere is solution heat treated to 800 °C (1475 °F) for 1 to 2 h in vacuum and water quenched
- Hemisphere is aged in argon at 200 °C (400 °F) for 2 h

Licensing and Health and Safety Requirements

Possession of more than 15 lb (6.8 kg) of depleted uranium in any form requires a license from the U.S. Nuclear Regulatory Commission. Title 10, Part 40, of Federal Regulations describes the steps necessary and the requirements to obtain such a license. In addition, all other local, state, and federal regulations are effective as applicable.

The greatest potential source of contamination in the heat-treating area is uranium oxide. The area should be isolated from the remainder of the plant, and everyone entering should be required to wear disposable protective footwear. Smoking and eating should be restricted.

Caution: The toxicity of depleted uranium if it enters the blood stream may result in poisoning similar to that caused by lead, arsenic, mercury, or any other heavy metal.

A more detailed discussion about health and safety requirements is provided in Volume 2 of *ASM Handbook*, formerly 10th Edition *Metals Handbook.* The important fact to remember is that each new operation or procedure involving uranium alloys should be individually evaluated to determine the correct protective clothing and equipment, dosimetry, and handling requirements for that particular job. The prior processing history of the heat treatment samples is likewise important in this consideration since operations which change the state of the uranium, like casting, can make concerns about daughter-product beta radiation more important than normal low-level alpha radiation associated with depleted uranium.

Annealing of Precious Metals

Gaylord Smith, Inco Alloys International, Inc.; Al Robertson, Englehard Corporation

Introduction

THE PRECIOUS METAL GROUP consists of silver, gold, platinum, palladium, rhodium, iridium, ruthenium, and osmium. Significant production of wrought product forms is limited to the first four elements and their alloys. The last four elements become increasingly intractable or less ductile and consequently cannot be practically fabricated into engineering products. Because of the dissimilarities of the physical metallurgy of elements within the precious metal group, the annealing practice for each member of the group will be considered separately. For each element and its alloys, a brief description of the compositions, uses, annealing practices, and nominal annealing effects on key properties is given.

Silver and Silver Alloys

Consumption of silver and silver alloys in wrought product form is large and exceeds that of any other members of the precious metal group. Because of the extensive use of silver, data on annealing practice and the effects of annealing on mechanical properties are more available for silver than for the remainder of the precious metal group.

Commercially Pure Fine Silver

Commercially pure fine silver contains, by definition, at least 99.9% Ag. It is widely used in the electrical and electronics industries as contacts and conductors and in the chemical industry as linings for reactors and process/storage vessels, particularly caustic evaporators and crystallizers.

Annealing Practice. Commercially pure fine silver is typically annealed between 300 and 350 °C (570 and 660 °F) following at least 50% cold work. However, data exists in the literature for annealing times up to 1.5 h at temperatures as high as 565 °C (1050 °F). Most annealing of silver, however, is done at approximately 500 °C (930 °F). Under extreme conditions of cold work, ultra-pure (99.99% pure) silver can recrystallize at temperatures as low as room temperature. Silver is typically annealed in air at temperatures below 350 °C (660 °F) without adverse effects. However, higher annealing temperatures (550 to 650 °C, or 1020 to 1200 °F) can result in oxygen adsorption due to the high solubility and diffusion rate (under 0.025 mm at >800 °C/h, or 1440 °F/h) of oxygen in silver. Very pure silver has a hardness of 25 HV after a hydrogen anneal at 650 °C (1200 °F) and 27 HV after annealing in air at the same temperature. Oxygen present in silver tends to react with impurities and has the beneficial effect of inhibiting grain growth. Silver containing oxygen will become embrittled when annealed in hydrogen. Hydrogen annealing of thin material sections of silver can cause the formation of blisters. This effect is similar to that known to occur when tough pitch copper, that is, copper refined in a reverberatory furnace to adjust the oxygen content to 0.2 to 0.5%, is annealed in hydrogen. Thus, deoxidized silver is essential where hydrogen annealing is practiced.

Effect of Annealing Temperature on Mechanical Properties. The effect of annealing temperature on the tensile strength and elongation of wire cold drawn 49% prior to annealing is presented in Fig. 1. Ductility is maximized at

approximately 370 °C (700 °F). Higher temperatures reduce ductility and ultimately increase tensile strength as grain growth and perhaps oxygen adsorption begin to adversely influence tensile properties. Comparable data are presented in Table 1 for commercially pure fine silver sheet, 0.81 mm (0.032 in.) thick. Data on the deep-drawing characteristics of commercially pure fine silver as a function of annealing temperature are given in Table 2. Annealing lowers Poisson's ratio to 0.37 from 0.39 for hard-drawn material. The most frequently reported room-temperature value for the elastic modulus of commercially pure fine silver is 71 GPa (10.3×10^6 psi). This value was determined on material strained 5% and then annealed 0.5 h at 350 °C (660 °F). Cold work and annealing temperature, as well as compositional variations, apparently can affect the elastic modulus. The shear modulus is reduced by annealing from the cold worked state from 26.9 GPa (3.90×10^6 psi) for hard-drawn material to 26.6 GPa (3.86×10^6 psi) for annealed commercially pure fine silver at 20 °C (68 °F).

Table 1 Effect of annealing temperature on room-temperature tensile properties of commercially pure fine silver cold rolled 50% to 0.81 mm (0.032 in.) thickness

Annealing condition (held $\frac{1}{2}$ h)		**Tensile strength**		**Elongation, %**

Effect of Cold Work on Recovery and Recrystallization. Data for the onset of softening (recovery) for commercially pure fine silver as a function of the degree of cold rolling at 20 °C (68 °F) are shown in Table 3. Commercially pure fine silver that has been cold worked extensively, that is, greater than about 95%, can recrystallize at relatively low temperatures. The effect of small amounts of a second element has been found to measurably influence the recrystallization temperature under these conditions. A brief summary of these observations is given in Table 4. Because

of the uncertainty of overall purity and whether the temperature given is the start or finish of recrystallization, these data are only indicative of a general trend.

Table 3 Effect of cold work on the softening temperature of commercially pure fine silver

Reduction by rolling at 20 °C (68 °F), %	Softening temperature	
	°C	°F
10	250	480
50	100	210
90	65	150

Silver-Copper Alloys

The most common silver-copper alloys are sterling silver (92.5% Ag minimum), coin silver (Ag-10% Cu), and the eutectic alloy containing 28.1% Cu. Sterling silver is normally alloyed only with copper because other elements have proved to be less effective hardeners. Sterling silver is typically used for flat and hollow tableware and in the manufacture of jewelry. Coin silver is used for coins and in certain electrical contacts where pure silver is deemed too soft and prone to pitting. Spring-type electrical contacts are made from the eutectic alloy.

Effect of Annealing Temperature on Mechanical Properties. Figure 2 shows the effect of annealing temperature on the strength and elongation of cold drawn 2.3 mm (0.091 in.) diam sterling silver and eutectic alloy wire. Commercial silver-copper alloys are typically annealed between 480 and 535 °C (900 and 1000 °F) followed by furnace cooling under protective atmosphere, which can result in some age hardening. Process annealing can be conducted at temperatures as high as 675 °C (1250 °F) usually in a steam atmosphere or salt bath. However, at the higher temperature, quenching is required for producing full softness. Alternating between oxidizing and reducing atmospheres during annealing is damaging to this alloy compositional range. Where light oxidation has occurred, pickling in a hot (approximately 50 °C, or 120 °F) sulfuric acid solution (5 to 10%) is suitable.

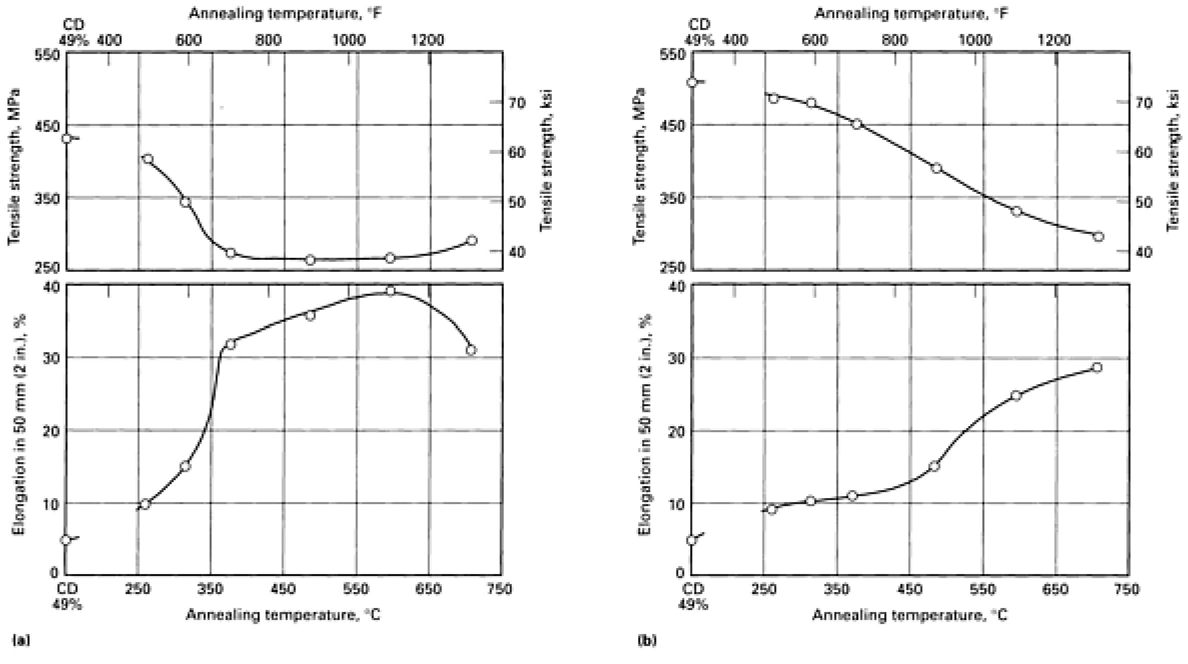

Fig. 2 Tensile properties and electrical conductivity of silver-copper alloys. 2.3 mm (0.091 in.) diam wire, cold drawn (CD) 49% before annealing. (a) Sterling silver (92.5Ag-7.5Cu). (b) Eutectic alloy (72Ag-28Cu)

Figure 3 records the nominal electrical resistivity of annealed as well as annealed/aged silver-copper wire as a function of copper content. The silver-copper alloys can be age hardened as depicted in Fig. 4. The solubility of copper in silver at 650 °C (1200 °F) is about 4% and at 730 °C (1350 °F) about 6%, thus sterling silver annealed at these temperatures is duplex with small amounts of the copper-rich phase scattered through the silver-rich matrix. Aging treatments cause precipitation of the copper-rich phase and, if prolonged, increase the electrical conductivity considerably. Coin silver will remain duplex after any annealing treatment, and ages in much the same manner as sterling silver. Both alloys respond to aging at 280 °C (535 °F) (Fig. 4). The mechanical properties of sterling silver and coin silver are virtually the same after the usual annealing treatment at about 650 °C (1200 °F) because the composition of the silver-rich phase is essentially the same. Alloys containing 20 to 30% Cu have much more of the copper-rich phase and show less age hardening.

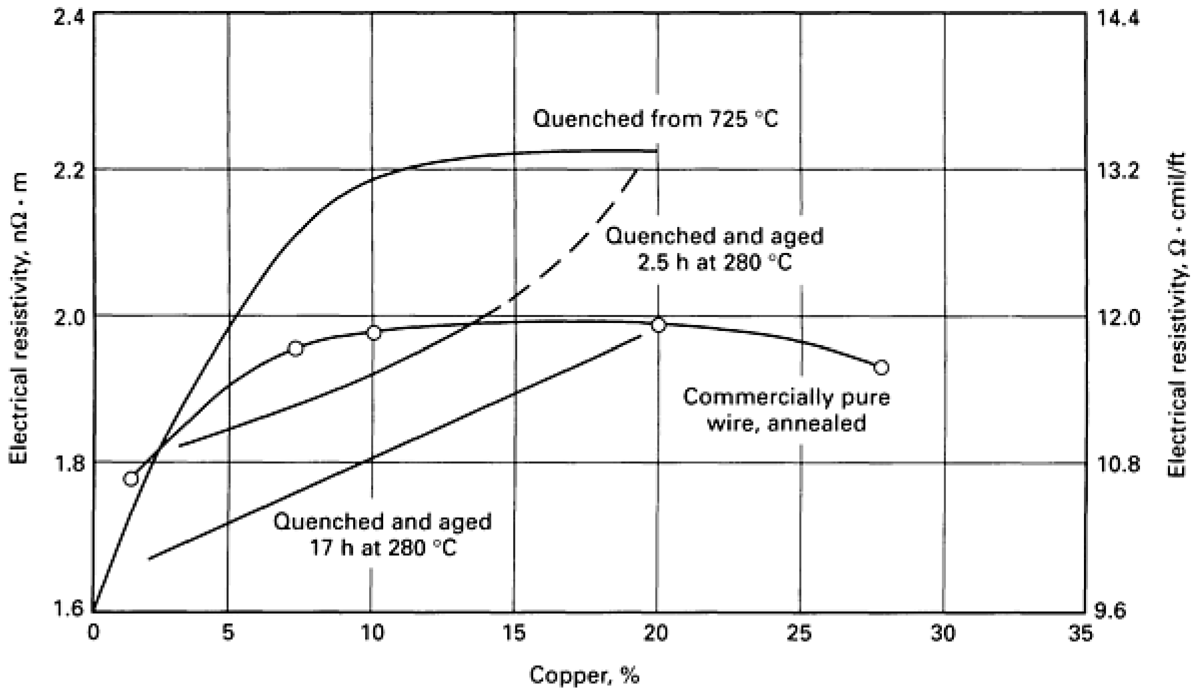

Fig. 3 Effect of copper content on the electrical resistivity of annealed silver-copper alloys and annealed/aged silver-copper alloys

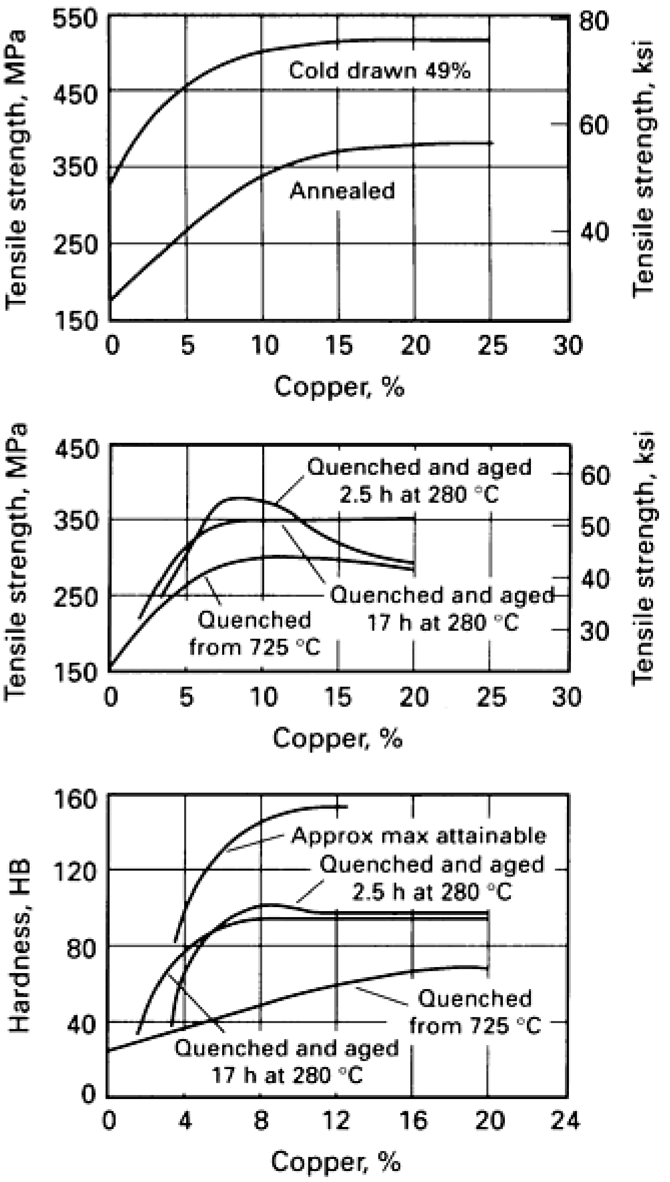

Fig. 4 Effect of copper content on properties of silver-copper alloys

Gold and Gold Alloys

There are a number of types of pure and alloy gold systems of commercial significance each with different annealing practices. Included here will be annealing information on pure gold, color and white gold, gold-platinum, gold-palladium-iron, and cast and wrought gold alloys for dentistry.

Pure Gold

The usual grade of refined gold is 99.99% pure and is suitable for jewelry and dental applications. Coin gold contains 89.9 to 91.7% Au, with the balance being copper.

Annealing Practice. Pure gold can be annealed in air at 305 °C (580 °F) to control grain size but it is usually not required because pure gold easily recrystallizes at room temperature. Wrought annealed pure gold has a room temperature tensile strength of 131 MPa (19 ksi), 45% elongation, and a hardness of 25 HB. The elastic modulus is 80 GPa (11.6×10^6 psi).

Color Gold Alloys

Most of the commercially important color gold alloys are based on the gold-silver-copper system although zinc and nickel are frequent modifiers. The composition of typical color gold alloys is given in Table 5. These alloys are used principally in jewelry; slip rings and bushings in electrical devices; and in dental applications.

Table 5 Chemical composition of typical color gold alloys

Alloy, k	Color	Nominal composition, wt%			
		Au	Cu	Ag	Zn
10	Yellow	41.7	43.8	5.5	9.0
10	Yellow	41.7	48.0	6.6	3.7
10	Yellow	41.7	40.8	11.7	5.8
10	Green	41.7	9.1	48.9	0.3
14	Yellow	58.3	31.3	4.0	6.4
14	Yellow	58.3	29.2	8.3	4.2
14	Yellow	58.3	39.7	10.0	2.0
14	Yellow	58.3	25.0	16.5	0.2
14	Yellow	58.3	16.8	24.8	0.1
14	Green	58.3	6.5	35.0	0.2
18	Yellow	75.0	10.0	15.0	. . .

Annealing Practice. Typical annealing temperatures for the color gold alloys are in the range of 500 to 700 °C (930 to 1290 °F) depending on the exact composition. It is recommended that color gold alloys be quenched in water after annealing to avoid age hardening. This has the secondary effect of removing any oxide scale that may have formed during

annealing in air. Commercially, most annealing of color gold alloys is done in a 7% H_2-N_2 atmosphere with slow cooling instead of quenching.

However, nickel-containing white gold alloys should be air cooled as quenching introduces high residual stress levels in these alloys. Aging of the two-phase alloys is customarily done at 260 to 315 °C (500 to 600 °F).

Effect of Annealing and Aging on Hardness. Figure 5 depicts the effect of annealing, followed by quenching, on the hardness of the color gold alloys. Also shown is the effect of aging at 260 to 315 °C (500 to 600 °F) as a function of silver content. Age hardening temperatures can vary from between 100 °C (210 °F) and 425 °C (800 °F) depending upon the alloy that is being used. Aging times can vary from 5 min to 2 h, with increasing time associated with increasing strength and lower ductility. Longer aging times may result in overaging and subsequent decreasing hardness. In Fig. 5, note the lack of an aging response for the extremes of the silver content for the 10 and 14 k alloys, where k is karats.

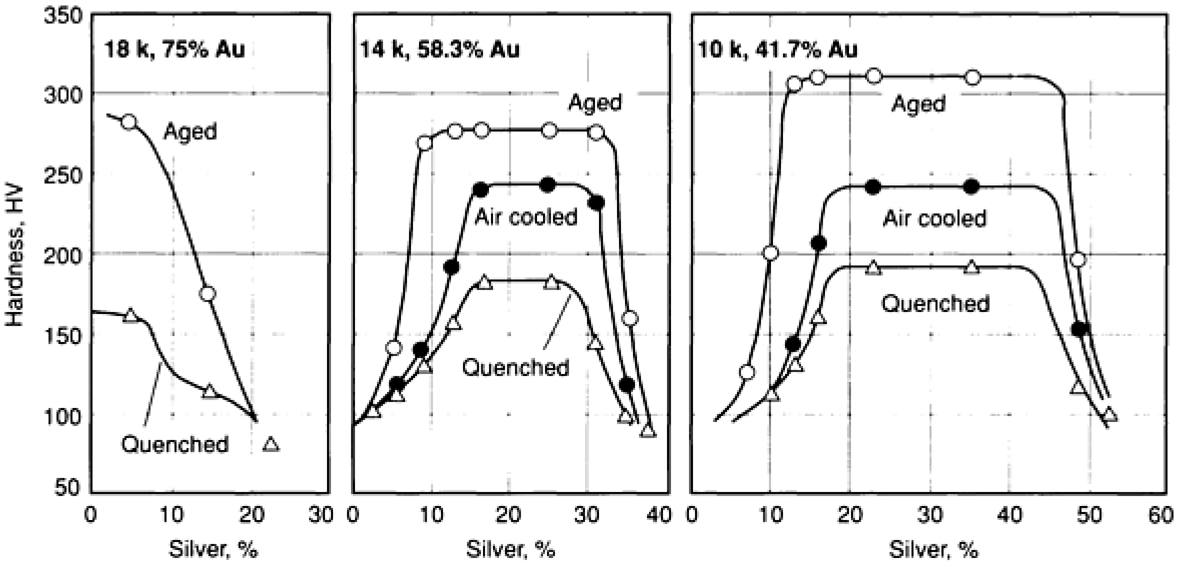

Fig. 5 Variation of hardness with silver content for gold-silver-copper alloys

Gold Alloys in Dentistry

A large number of alloys are used in dentistry in the form of wrought plate and wire, casting, and solder. These alloys require high strength and corrosion resistance. Both requirements are met by complex alloys of gold, platinum, palladium, silver, copper, and zinc. These alloys age harden readily. Typical compositional limits of wrought alloys are given in Table 6 and for cast alloys in Table 7.

Annealing Practice. The wrought alloys are typically annealed and quenched from 705 to 870 °C (1300 to 1600 °F). Aging of these alloys can be accomplished by cooling slowly and uniformly from 450 to 250 °C (840 to 480 °F). Manufacturer recommendations for each alloy must be carefully followed for specific mechanical properties. The cast gold alloys used in dentistry are annealed by heating to 705 °C (1300 °F) for 10 min and quenching in water. Reheating to

450 °C (840 °F) in about 30 min will produce maximum strength and hardness with loss of considerable ductility. Surface discoloration can be removed by pickling in 15% HC1 or hot 50% H_2SO_4.

Effect of Annealing and Aging. The annealed and aged physical and mechanical properties of wrought gold alloys for dental applications are presented in Table 8. The properties for the cast gold alloys are given in Table 9.

Gold-Palladium-Iron Alloys

Selected alloys within the gold-palladium-iron ternary system develop exceptionally high resistivity with proper heat treatment. There is a peak in the resistivity in the central area of the loops shown in Fig. 6. The maximum resistivity of 180 μ · cm (1100 · cmil/ft) is found after heat treatment at 49.5% Au, 40.5% Pd, and 10% Fe. These alloys are used primarily for potentiometer wire.

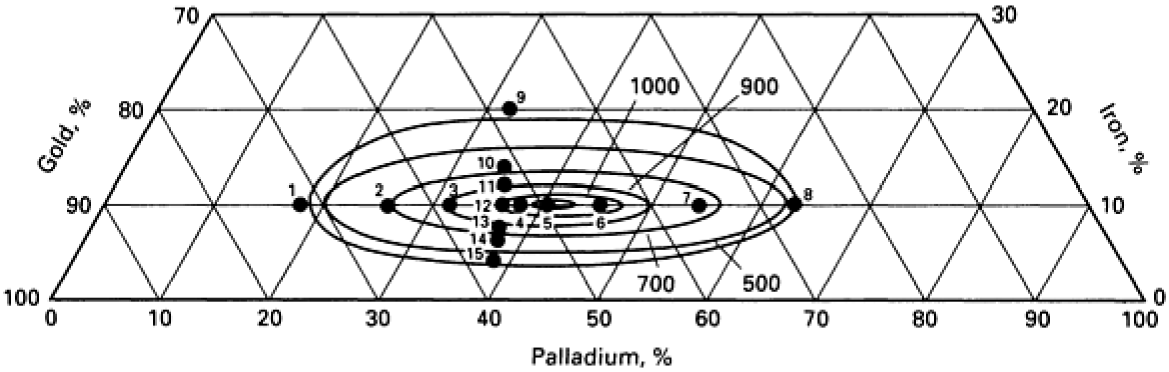

Fig. 6 Curves of equal resistivity for gold-platinum-iron alloys annealed 1 h at 500 °C (930 °F). Numbers from 1 to 15 refer to alloys for which resistivity is shown in Table 10. Numbers 500 to 1000 refer to resistivity values given in ohm · circular mils/ft

Annealing Practice. Peak resistivity is generally achieved by annealing cold worked material at 500 °C (930 °F) for 1 h. Higher temperatures result in lower resistivity values and lower temperatures require longer times to reach peak resistivity.

Effect of Annealing on Resistivity. Table 10 presents the resistivity of the alloys of Fig. 6 as cold worked (about 50%) and as annealed for 1 h at 500 °C (930 °F). The tensile strength of the peak resistivity alloy is 1380 MPa (200 ksi) as heat treated and 690 MPa (100 ksi) as cold worked.

Table 10 Electrical resistivity of gold-platinum-iron alloys shown in Fig. 6

Platinum Group Elements and Alloys

The platinum group metals are used in a wide range of applications and product forms. Applications for wrought products include electrical contacts, brushes, precision potentiometer wire, laboratory ware, thermocouple alloys, catalysts, anodes, spinnerets, crucibles, sputter targets, spark plugs, igniters, fiberglass bushings, and magnets.

Platinum and Platinum Alloys

Platinum is the best known and least rare of the platinum group metals and has the widest range of uses because of its general corrosion resistance, high melting point, appearance, and ductility.

Annealing Practice. The annealing temperature range for platinum is 600 to 1000 °C (1110 to 1830 °F). The most common commercial annealing practice is torch annealing. The maintenance of oxidizing conditions throughout the anneal is essential to avoid contamination. Hot reducing atmospheres can contaminate pure platinum and contact with asbestos pads or charcoal is not recommended. Alumina supports work well. For high-purity wire and sheet, it is essential to remove iron contamination after processing and before annealing by pickling in hot hydrochloric acid. The entire range of platinum-palladium alloys can be annealed at 900 °C (1650 °F). However, the palladium-rich alloys should be annealed in inert or nitrogen atmospheres. Platinum-rhodium alloys containing 3.5 to 40% Rh are typically annealed between 900 and 1000 °C (1650 and 1830 °F). Platinum-iridium alloys containing 0.4 to 10% Ir are commonly annealed between 1000 and 1200 °C (1830 and 2190 °F). For alloys of higher iridium content, temperatures nearer 1400 °C (2550 °F) are recommended. Platinum alloys containing more than 10% Ir can be age hardened by quenching from 1700 °C (3090 °F) followed by heating to 805 °C (1480 °F). Pt-5% Ru can be annealed at 1000 °C (1830 °F) and Pt-10% Ru at 1100 °C (2010 °F).

Pt-23% Co and similar alloys close to the 50/50 atomic composition can be annealed by quenching from above the transformation temperature of 830 °C (1525 °F). Optimum magnetic properties can be developed in these materials by following quenching with a heat treatment designed to develop partial ordering in the system.

Effects of Annealing on Mechanical Properties. The hardness of commercially pure platinum (99.95% min) and chemically pure platinum (99.99% min) as a function of annealing temperature for various percent reductions is plotted in Fig. 7. The tensile strength and hardness of annealed and cold worked platinum-palladium compositions as a function of palladium content are given in Fig. 8 and 9. Table 11 presents the annealed and cold worked properties of the common platinum-rhodium alloys and Table 12 presents these properties for the common platinum-iridium alloys. Figure 10 shows the tensile strength of platinum-ruthenium alloys in the annealed and cold worked condition as a function of ruthenium content.

Palladium and Palladium Alloys

While palladium resembles platinum in appearance and tensile properties, its corrosion resistance and melting point are lower. The major use of palladium and its alloys has been for contacts in light-duty relays, where its freedom from tarnish and cold fusion provides extreme reliability and noise-free transmission. Palladium hardened with ruthenium provides an all precious metal white jewelry alloy that sets off diamonds to advantage.

Palladium dental casting alloys have, to a great extent, replaced the high gold dental casting alloys as the material of choice for porcelain bonding and other dental restoration work. Palladium-silver alloys are used for the production of high-purity hydrogen by taking advantage of the selective high diffusion rate of this gas through the alloy.

Annealing Practice. Commercially pure palladium (99.85% min) can be annealed at about 800 °C (1470 °F). Nitrogen-hydrogen mixtures, nitrogen, argon, or steam provide a suitable annealing atmosphere. Slow cooling in air from 815 °C (1500 °F) to 425 °C (800 °F) will cause a blue oxide film to form. To avoid this, the metal should be quenched in water or cooled in a nitrogen atmosphere. Cooling in hydrogen will cause a phase change to occur with accompanying distortions. Alloys in the palladium-silver-copper system can be annealed at about 800 °C (1470 °F) in nitrogen. The age hardenable alloys in this system (see Fig. 11) should be cooled fairly rapidly for maximum softness. If much zinc is present, oil quenching may be required. Treatment for $\frac{1}{4}$ to 5 h between 400 and 500 °C (750 and 930 °F) hardens most of these alloys effectively. Alloys in the palladium-silver-gold system can be annealed at 850 °C (1560 °F) in nitrogen. Pd-4.5% Ru is effectively annealed in a N_2-36.7% H_2 atmosphere at 900 °C (1650 °F).

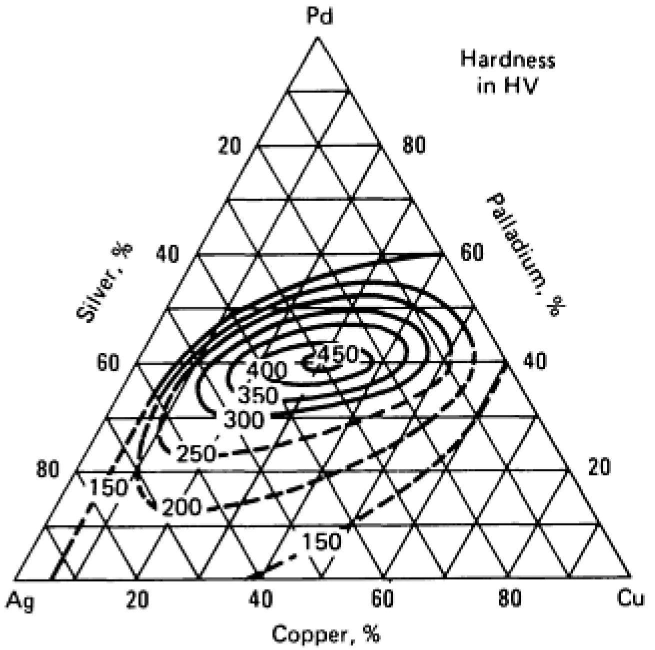

Fig. 11 Maximum hardness of aged palladium-silver-copper alloys

Effect of Annealing on Mechanical Properties. The tensile properties of cold drawn deoxidized palladium as a function of annealing temperature are presented in Fig. 12. The hardness of commercially pure (99.85% min) and chemically pure (99.99% min) palladium versus annealing temperature are given in Fig. 13 for various degrees of reduction. The tensile strength and hardness of annealed and cold worked palladium-silver alloys as a function of silver content are shown in Fig. 14. The maximum hardness of aged palladium-silver-copper alloys is shown in Fig. 15. The effect of annealing temperature on the tensile properties of Pd-4.5% Ru are shown in Fig. 16.

Rhodium, Iridium, and Ruthenium

Wrought products of these elements are produced although not to the extent that platinum and palladium are produced. Iridium and rhodium can be produced using arc melting and electron-beam (EB) furnaces. These elements can be produced using powder metallurgy, although generally only ruthenium is fabricated via powder metallurgy.

Annealing Practice. These elements must be annealed in an inert atmosphere or vacuum to prevent oxidation. Commercial iridium and ruthenium can be annealed at 1315 °C (2400 °F).

Effect of Annealing on Hardness. The hardness of commercial rhodium, iridium, and ruthenium as a function of annealing temperature for varying degrees of cold work is given in Fig. 17.

Introduction

It is common and long-time knowledge that steel heated in contact with air at temperatures in the tempering range takes on various temper colors due to the formation of a thin oxide film. There is, however, little detailed information on this phenomenon in the readily available literature. As an example, the 1948 ASM *Metals Handbook* gives the following table:

Heating temperature, °F	Color
400	Faint straw
440	Straw
475	Deep straw
520	Bronze
540	Peacock
590	Full blue
640	Light blue

Temper Colors

In the course of a research program at the Illinois Institute of Technology, it became desirable to have more detailed information on temper colors for plain carbon steel, especially on the effect of time and temperature. This was obtained using 16 mm ($\frac{5}{8}$ in.) diam hot-rolled bars of a standard SAE 1035 steel. Samples that were 50 mm (2 in.) long were cut from the bars and carefully machined and cleaned to give smooth, bright surfaces. They were then heated for various times at several temperatures in air-circulating furnaces controlled to within ±3 °C (±5 °F) of the desired temperatures. The results of this study are shown in Fig. 1.

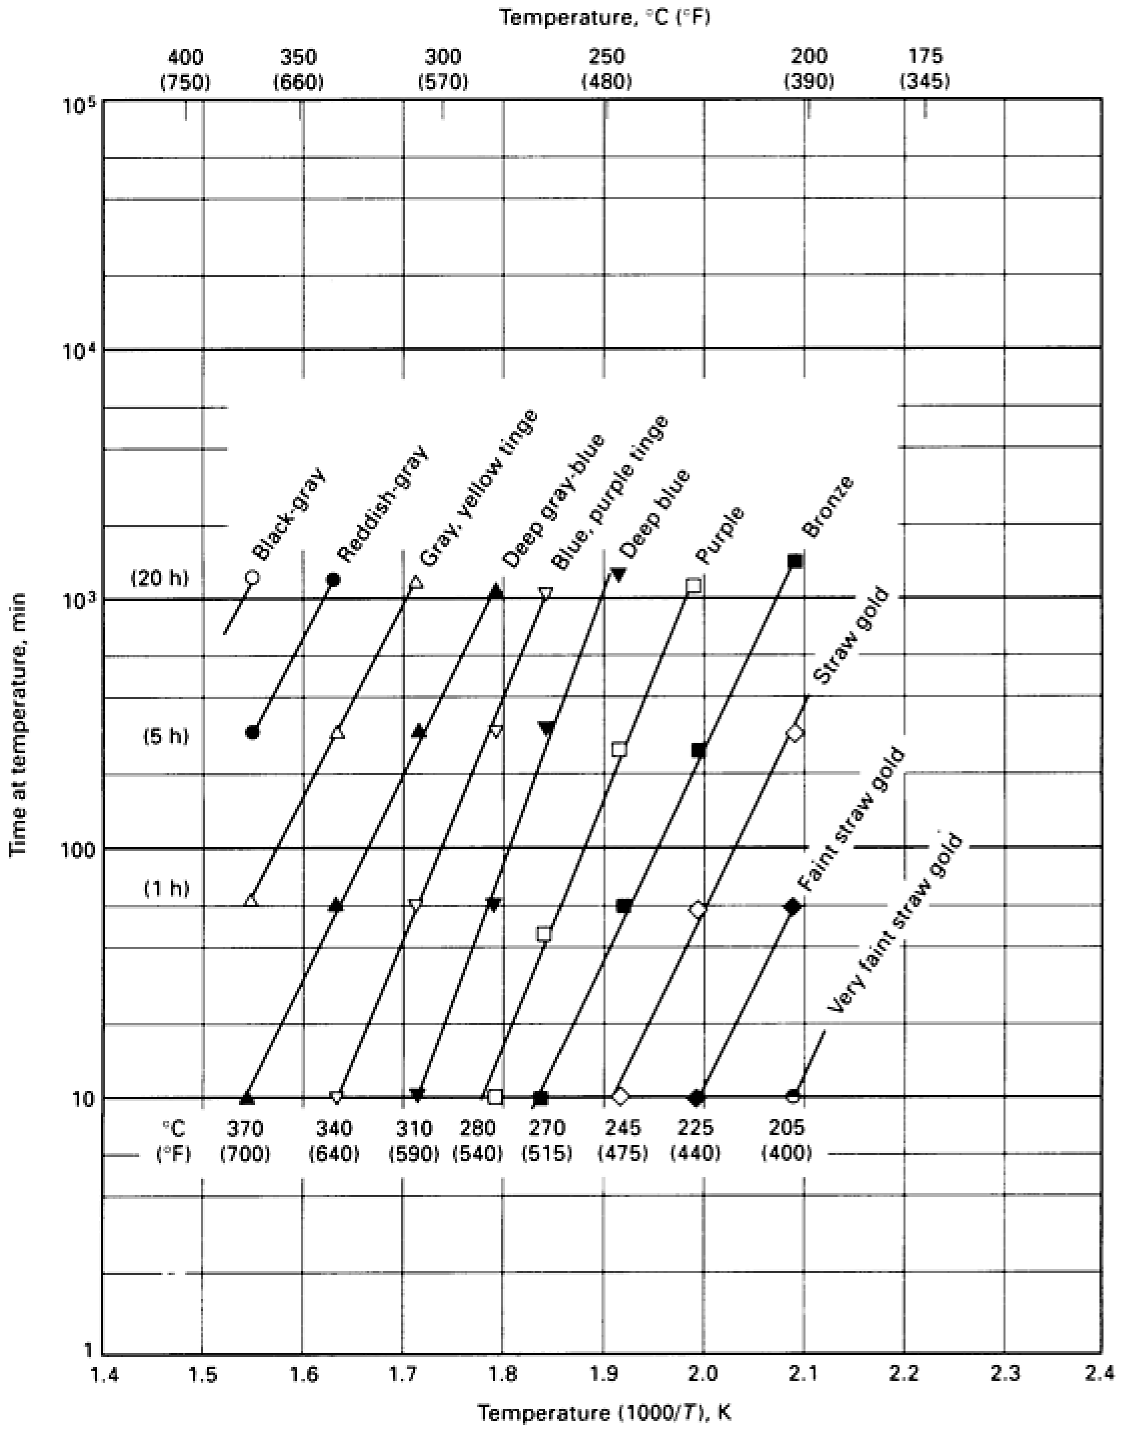

Fig. 1 Temper colors after heating 1035 steel in circulating air (atmospheric pressure)

Austenitizing Temperatures for Steels

Introduction

Temperatures recommended for austenitizing carbon and low-alloy steels prior to hardening are given in Table 1 (for direct-hardening grades) and Table 2 (for carburized steels). Table 2 is applicable to carburized steels that have been cooled slowly from the carburizing temperature and are to be furnace hardened in a subsequent operation.

Table 1 Austenitizing temperatures for direct-hardening carbon and alloy steels (SAE)

(a) Commonly used on parts where induction hardening is employed. All steels from SAE 1030 up may have induction hardening applications.

(b) This temperature range may be employed for 1095 steel that is to be quenched in water, brine, or oil. For oil quenching, 1095 steel may alternatively be austenitized in the range 815 to 870 °C (1500 to 1600 °F).

(c) This range is recommended for steel that is to be water quenched. For oil quenching, steel should be austenitized in the range 815 to 870 °C (1500 to 1600 °F).

Table 2 Reheating (austenitizing) temperatures for hardening of carburized carbon and alloy steels (SAE)

Carburizing is commonly carried out at 900 to 925 °C (1650 to 1700 °F); slow cooled and reheated to given austenizing temperature.

For most applications, the rate of heating to the austenitizing temperature is less important than other factors in the hardening process, such as maximum temperature attained throughout the section, temperature uniformity, time at temperature, and rate of cooling. The thermal conductivity of the steel, the nature of the furnace atmosphere (scaling or nonscaling), thickness of section, method of loading (spaced or stacked), and the degree of circulation of the furnace atmosphere all influence the rate of heating of the steel part to the required temperature selected from Tables 1 and 2.

Temperature Rise

The difference in temperature rise within thick and thin sections of articles of varying cross section is a major problem in practical heat-treating operations. When temperature uniformity is the ultimate objective of the heating cycle, this is more safely attained by slowly heating than by rapidly heating. Furthermore, the maximum temperature in the austenite range should not exceed that required to achieve the necessary extent of solution of carbide. The temperatures listed in Tables 1 and 2 conform with this requirement. When heating with significant cross-section variations, provisions should be made for slower heating to minimize thermal stresses and distortions.

Glossary of Terms

- **A**

- **A_{cm}, A_1, A_3, A_4**
  - Same as Ae_{cm}, Ae_1, and Ae_3 and Ae_4.
- **Ac_{cm}, Ac_1, Ac_3, Ac_4**
  - Defined under transformation temperature .
- **acicular ferrite**
  - A highly substructured non-equiaxed ferrite that forms upon continuous cooling by a mixed diffusion and shear mode of transformation that begins at a temperature slightly higher than the temperature transformation range for upper bainite. It is distinguished from bainite in that it has a limited amount of carbon available; thus, there is only a small amount of carbide present.
- **Ae_{cm}, Ae_1, Ae_3, Ae_4**
  - Defined under transformation temperature .
- **aerated bath nitriding**
  - A type of liquid nitriding in which air is pumped through the molten bath creating agitation and increased chemical activity.
- **age hardening**
  - Hardening by aging, usually after rapid cooling or cold working. See aging .
- **age softening**
  - Spontaneous decrease of strength and hardness that takes place at room temperature in certain strain hardened alloys, especially those of aluminum.

- **aging**
  - A change in the properties of certain metals and alloys that occurs at ambient or moderately elevated temperatures after hot working or a heat treatment (quench aging in ferrous alloys, natural or artificial aging in ferrous and nonferrous alloys) or after a cold working operation (strain aging). The change in properties is often, but not always, due to a phase change (precipitation), but never involves a change in chemical composition of the metal or alloy. See also age hardening , artificial aging , interrupted aging , natural aging , overaging , precipitation hardening , precipitation heat treatment , progressive aging , quench aging , step aging .
- **air-hardening steel**
  - A steel containing sufficient carbon and other alloying elements to harden fully during cooling in air or other gaseous mediums from a temperature above its transformation range. The terms should be restricted to steels that are capable of being hardened by cooling in air in fairly large sections, about 2 in. (50 mm) or more in diameter. Same as self-hardening steel.
- **allotropy**
  - A near synonym for polymorphism . Allotropy is generally restricted to describing polymorphic behavior in elements, terminal phases, and alloys whose behavior closely parallels that of the predominant constituent element.
- **alpha ferrite**
  - See ferrite .
- **alpha iron**
  - The body-centered cubic form of pure iron, stable below 910 °C (1670 °F).
- **annealing**
  - A generic term denoting a treatment, consisting of heating to and holding at a suitable temperature followed by cooling at a suitable rate, used primarily to soften metallic materials, but also to simultaneously produce desired changes in other properties or in microstructure. The purpose of such changes may be, but is not confined to: improvement of machinability, facilitation of cold work, improvement of mechanical or electrical properties, and/or increase in stability of dimensions. When the term is used without qualification, full annealing is implied. When applied only for the relief of stress, the process is properly called stress relieving or stress-relief annealing.

    In ferrous alloys, annealing usually is done above the upper critical temperature, but the time-temperature cycles vary widely in both maximum temperature attained and in cooling rate employed, depending on composition, material condition, and results desired. When applicable, the following commercial process names should be used: black annealing , blue annealing , box annealing , bright annealing , cycle annealing , flame annealing , full annealing , graphitizing , intercritical annealing , isothermal annealing , malleablizing , order hardening , process annealing , quench annealing , spheroidizing , subcritical annealing .

    In nonferrous alloys, annealing cycles are designed to: (a) remove part or all of the effects of cold working (recrystallization may or may not be involved); (b) cause substantially complete coalescence of precipitates from solid solution in relatively coarse form; or (c) both, depending on composition and material condition. Specific process names in commercial use are final annealing , full annealing , intermediate annealing , partial annealing , recrystallization annealing , stress relieving ,anneal to temper .
- **annealing carbon**
  - Fine, apparently amorphous carbon particles formed in white cast iron and certain steels during prolonged annealing. Also called temper carbon.
- **annealing twin**
  - A twin form in a crystal during recrystallization.
- **anneal to temper**
  - A final partial anneal that softens a cold worked nonferrous alloy to a specified level of hardness or tensile strength.
- **Ar_{cm}, Ar_1, Ar_3, Ar_4, Ar', Ar''**
  - Defined under transformation temperature .
- **artificial aging**
  - Aging above room temperature. See aging . Compare with natural aging .

- **athermal transformation**
  - A reaction that proceeds without benefit of thermal fluctuations; that is, thermal activation is not required. In contrast, a reaction that occurs at constant temperature is an isothermal transformation ; thermal activation is necessary in this case and the reaction proceeds as a function of time.
- **ausforming**
  - Thermomechanical treatment of steel in the metastable austenitic condition below the recrystallization temperature followed by quenching to obtain martensite and/or bainite.
- **austempering**
  - A heat treatment for ferrous alloys in which a part is quenched from the austenitizing temperature at a rate fast enough to avoid formation of ferrite or pearlite and then held at a temperature just above M_s until transformation to bainite is complete. Although designated as bainite in both austempered steel and austempered ductile iron (ADI), austempered steel consists of two phase mixtures containing ferrite and carbide, while austempered ductile iron consists of two phase mixtures containing ferrite and austenite.
- **austenite**
  - A solid solution of one or more elements in face-centered cubic iron. Unless otherwise designated (such as nickel austenite), the solute is generally assumed to be carbon.
- **austenitic grain size**
  - The size attained by the grains of steel when heated to the austenitic region; may be revealed by appropriate etching of cross sections after cooling to room temperature.
- **austenitizing**
  - Forming austenite by heating a ferrous alloy into the transformation range (partial austenitizing) or above the transformation range (complete austenitizing). When used without qualification, the term implies complete austenitizing.
- **B**
- **bainite**
  - A metastable aggregate consisting of dispersed carbide in ferrite resulting from the transformation of austenite at temperatures below the pearlite range but above M_s. Its appearance is in the form of relatively coarse ferrite laths between which carbides are precipitated as platelets if formed in the upper part of the bainite transformation range; acicular, resembling tempered martensite, if formed in the lower part.
- **bainitic hardening**
  - Quench-hardening treatment resulting principally in the formation of bainite .
- **batch furnace**
  - A furnace used to heat treat a single load at a time. Batch-type furnaces are necessary for large parts such as heavy forgings and are preferred for complex alloy grades requiring long cycles. See car furnace , horizontal batch furnace .
- **belt furnace**
  - A continuous-type furnace which uses a mesh-type or cast-link belt to carry parts through the furnace.
- **beta annealing**
  - Producing a beta phase by heating certain titanium alloys in the temperature range of which this phase forms followed by cooling at an appropriate rate to prevent its decomposition.
- **black annealing**
  - Box annealing or pot annealing ferrous alloy sheet, strip, wire to impart a black color to the oxidized surface. See box annealing .
- **black oxide**
  - A black finish on a metal produced by immersing it in hot oxidizing salts or salt solutions.
- **blank carburizing**
  - Simulating the carburizing operation without introducing carbon. This is usually accomplished by using an inert material in place of the carburizing agent, or by applying a suitable protective coating to the ferrous alloy.
- **blank nitriding**
  - Simulating the nitriding operation without introducing nitrogen. This is usually accomplished by using an inert material in place of the nitriding agent or by applying a suitable protective coating to the ferrous alloy.
- **blue annealing**

- Heating hot-rolled ferrous sheet in an open furnace to a temperature within the transformation range and then cooling in air, in order to soften the metal. The formation of a bluish oxide on the surface is incidental.

- **blue brittleness**
  - Brittleness exhibited by some steels after being heated to some temperature within the range of about 205 to 370 °C (400 to 700 °F), particularly if the steel is worked at the elevated temperature. Killed steels are virtually free of this kind of brittleness.
- **bluing**
  - Subjecting the scale-free surface of a ferrous alloy to the action of air, steam, or other agents at a suitable temperature, thus forming a thin blue film of oxide and improving the appearance and resistance to corrosion. Note: This term is ordinarily applied to sheet, strip, or finished parts. It is used also to denote the heating of springs after fabrication to improve their properties.
- **boriding**
  - Thermochemical treatment involving the enrichment of the surface layer of an object with borides. This surface-hardening process is performed below the Ac_1 temperature.
- **boronizing**
  - See boriding .
- **box annealing**
  - Annealing a metal or alloy in a sealed container under conditions that minimize oxidation. In box annealing a ferrous alloy, the charge is usually heated slowly to a temperature below the transformation range, but sometimes above or within it, and is then cooled slowly; this process is also called close annealing or pot annealing. See black annealing .
- **breaks**
  - Creases or ridges usually in "untempered" or in aged material where the yield point has been exceeded. Depending on the origin of the break, it may be termed a cross break, a coil break, an edge break, or a sticker break.
- **bright annealing**
  - Annealing in a protective medium to prevent discoloration of the bright surface.
- **bright nitriding**
  - Nitriding in a protective medium to prevent discoloration of the bright surface. Compare with blank nitriding .
- **brine quenching**
  - A quench in which brine (salt water-chlorides, carbonates, and cyanides) is the quenching medium. The salt addition improves the efficiency of water at the vapor phase or hot stage of the quenching process.
- **brittle fracture**
  - Separation of a solid accompanied by little or no macroscopic plastic deformation. Typically, brittle fracture occurs by rapid crack propagation with less expenditure of energy than for ductile fracture .
- **burning**
  - (1) Permanently damaging a metal or alloy by heating to cause either incipient melting or intergranular oxidation. See overheating , grain-boundary liquation. (2) In grinding, getting the work hot enough to cause discoloration or to change the microstructure by tempering or hardening.
- **C**
- **calorizing**
  - Imparting resistance to oxidation to an iron or steel surface by heating in aluminum powder at 800 to 1000 °C (1470 to 1830 °F).
- **carbonitriding**
  - A case hardening process in which a suitable ferrous material is heated above the lower transformation temperature in a gaseous atmosphere of such composition as to cause simultaneous absorption of carbon and nitrogen by the surface and, by diffusion, create a concentration gradient. The process is completed by cooling at a rate that produces the desired properties in the workpiece.
- **carbonization**
  - Conversion of an organic substance into elemental carbon. (Should not be confused with car*bur*ization.)
- **carbon potential**

- A measure of the ability of an environment containing active carbon to alter or maintain, under prescribed conditions, the carbon level of the steel. Note: In any particular environment, the carbon level attained will depend on such factors as temperature, time, and steel composition.

- **carbon restoration**
  - Replacing the carbon lost in the surface layer from previous processing by carburizing this layer to substantially the original carbon level. Sometimes called recarburizing.
- **carburizing**
  - Absorption and diffusion of carbon into solid ferrous alloys by heating, to a temperature usually above Ac_3, in contact with a suitable carbonaceous material. A form of case hardening that produces a carbon gradient extending inward from the surface, enabling the surface layer to be hardened either by quenching directly from the carburizing temperature or by cooling to room temperature, then reaustenitizing and quenching.
- **carburizing flame**
  - A gas flame that will introduce carbon into some heated metals, as during a gas welding operation. A carburizing flame is a reducing flame , but a reducing flame is not necessarily a carburizing flame.
- **car furnace**
  - A batch-type furnace using a car on rails to enter and leave the furnace area. Car furnaces are used for lower stress relieving ranges.
- **case**
  - That portion of a ferrous alloy, extending inward from the surface, whose composition has been altered so that it can be case hardened. Typically considered to be the portion of the alloy (a) whose composition has been measurably altered from the original composition, (b) that appears dark on an etched cross section, or (c) that has a hardness, after hardening, equal to or greater than a specified value. Contrast with core .
- **case hardening**
  - A generic term covering several processes applicable to steel that change the chemical composition of the surface layer by absorption of carbon, nitrogen, or a mixture of the two and, by diffusion, create a concentration gradient. The processes commonly used are carburizing and quench hardening; cyaniding; nitriding; and carbonitriding. The use of the applicable specific process name is preferred.
- **caustic quenching**
  - Quenching with aqueous solutions of 5 to 10% sodium hydroxide (NaOH).
- **CCT diagram**
  - See continuous cooling transformation diagram .
- **cementation**
  - The introduction of one or more elements into the outer portion of a metal object by means of diffusion at high temperature.
- **cementite**
  - A compound of iron and carbon, known chemically as iron carbide and having the approximate chemical formula Fe_3C. It is characterized by an orthorhombic crystal structure. When it occurs as a phase in steel, the chemical composition will be altered by the presence of manganese and other carbide-forming elements.
- **checks**
  - Numerous, very fine cracks in a coating or at the surface of a metal part. Checks may appear during processing or during service and are most often associated with thermal treatment or thermal cycling. Also called check marks, checking, heat checks.
- **close annealing**
  - Same as box annealing .
- **coalescence**
  - Growth of grains at the expense of the remainder by absorption or the growth of a phase or particle at the expense of the remainder by absorption or reprecipitation.
- **coarsening**
  - An increase in the grain size, usually, but not necessarily, by grain growth .
- **coherent precipitate**
  - A crystalline precipitate that forms from solid solution with an orientation that maintains continuity between the crystal lattice of the precipitate and the lattice of the matrix, usually

accompanied by some strain in both lattices. Because the lattices fit at the interface between precipitate and matrix, there is no discernible phase boundary.

- **cold die quenching**
  - A quench utilizing cold, flat, or shaped dies to extract heat from a part. Cold die quenching is slow, expensive, and is limited to smaller parts with large surface areas.
- **cold dry die quenching**
  - Same as cold die quenching .
- **cold treatment**
  - Treatment carried out after quenching to transform retained austenite into martensite, involving cooling and holding at a temperature below ambient.
- **columnar structure**
  - A coarse structure of parallel elongated grains formed by unidirectional growth, most often observed in castings, but sometimes in structures resulting from diffusional growth accompanied by a solid-state transformation.
- **combined carbon**
  - The part of the total carbon in steel or cast iron that is present as other than free carbon .
- **conditioning heat treatment**
  - A preliminary heat treatment used to prepare a material for desired reaction to a subsequent heat treatment. For the term to be meaningful, the exact heat treatment must be specified.
- **congruent transformation**
  - An isothermal or isobaric phase change in which both of the phases concerned have the same composition throughout the process.
- **constitution diagram**
  - See phase diagram .
- **continuous cooling transformation (CCT) diagram**
  - Set of curves drawn using logarithmic time and linear temperature as coordinates, which define for each cooling curve the beginning and end of the transformation of the initial phase.
- **continuous precipitation**
  - Precipitation from a supersaturated solid solution in which the precipitate particles grow by long-range diffusion without recrystallization of the matrix. Continuous precipitates grow from nuclei distributed more or less uniformly throughout the matrix. They usually are randomly oriented, but may form a Widmanstätten structure. Also called general precipitation. Compare with discontinuous precipitation , localized precipitation .
- **continuous-type furnace**
  - A furnace used for heat treating materials that progress continuously through the furnace, entering one door and being discharged from another. See belt furnace , direct-fired tunnel-type furnace , rotary retort furnace , shaker-hearth furnace .
- **controlled cooling**
  - Cooling from an elevated temperature in a predetermined manner, to avoid hardening, cracking, or internal damage, or to produce desired microstructure or mechanical properties.
- **cooling curve**
  - A curve showing the relation between time and temperature during the cooling of a material.
- **cooling stresses**
  - Residual stresses resulting from nonuniform distribution of temperature during cooling.
- **core**
  - In a ferrous alloy prepared for case hardening , that portion of the alloy that is not part of the case . Typically considered to be the portion that (a) appears light on an etched cross section, (b) has an essentially unaltered chemical composition, or (c) has a hardness, after hardening, less than a specified value.
- **critical cooling rate**
  - The rate of continuous cooling required to prevent undesirable transformation. For steel, it is the minimum rate at which austenite must be continuously cooled to suppress transformations above the M_s temperature.
- **critical diameter**
  - (*D*) Diameter of the bar that can be fully hardened with 50% martensite at its center.
- **critical point**
  - (1) The temperature or pressure at which a change in crystal structure, phase or physical properties occurs. Same as transformation temperature . (2) In an equilibrium diagram, that

specific value of composition, temperature and pressure, or combinations thereof, at which the phases of a heterogeneous system are in equilibrium.

- **critical strain**
  - The strain just sufficient to cause recrystallization ; because the strain is small, usually only a few percent, recrystallization takes place from only a few nuclei, which produces a recrystallized structure consisting of very large grains.
- **critical temperature**
  - (1) Synonymous with critical point if the pressure is constant. (2) The temperature above which the vapor phase cannot be condensed to liquid by an increase in pressure.
- **critical temperature ranges**
  - Synonymous with transformation ranges , which is the preferred term.
- **cryogenic treatment**
  - See cold treatment .
- **Curie temperature**
  - The temperature of magnetic transformation below which a metal or alloy is ferromagnetic and above which it is paramagnetic.
- **cyaniding**
  - A case-hardening process in which a ferrous material is heated above the lower transformation range in a molten salt containing cyanide to cause simultaneous absorption of carbon and nitrogen at the surface and, by diffusion, create a concentration gradient. Quench hardening completes the process.
- **cycle annealing**
  - An annealing process employing a predetermined and closely controlled time-temperature cycle to produce specific properties or microstructures.
- D
- **dead soft**
  - A temper of nonferrous alloys and some ferrous alloys corresponding to the condition of minimum hardness and tensile strength produced by full annealing .
- **decalescence**
  - A phenomenon, associated with the transformation of alpha iron to gamma iron on the heating (superheating) of iron or steel, revealed by the darkening of the metal surface owing to the sudden decrease in temperature caused by the fast absorption of the latent heat of transformation. Contrast with recalescence .
- **decarburization**
  - Loss of carbon from the surface layer of a carbon-containing alloy due to reaction with one or more chemical substances in a medium that contacts the surface.
- **degrees of freedom**
  - The number of independent variables (such as temperature, pressure, or concentration within the phases present) that may be altered at will without causing a phase change in an alloy system at equilibrium; or the number of such variables that must be fixed arbitrarily to define the system completely.
- **delta ferrite**
  - See ferrite .
- **dew point**
  - The temperature and pressure at which a gas begins to condense to a liquid.
- **dew point analyzer**
  - An atmosphere monitoring device that measures the partial pressure of water vapor in an atmosphere.
- **differential heating**
  - Heating that intentionally produces a temperature gradient within an object such that, after cooling, a desired stress distribution or variation in properties is present within the object.
- **diffusion**
  - (1) Spreading of a constituent in a gas, liquid, or solid, tending to make the composition of all parts uniform. (2) The spontaneous movement of atoms or molecules to new sites within a material.
- **diffusion coefficient**
  - A factor of proportionality representing the amount of substance diffusing across a unit area through a unit concentration gradient in unit time.

- **dilatometer**
  - An instrument for measuring the linear expansion or contraction in a metal resulting from changes in such factors as temperature and allotropy.
- **direct-fired tunnel-type furnace**
  - A continuous-type furnace where the work is conveyed through a tunnel-type heating zone, and the parts are hung on hooks or fixtures to minimize distortion.
- **direct quenching**
  - (1) Quenching carburized parts directly from the carburizing operation. (2) Also used for quenching pearlitic malleable parts directly from the malleablizing operation.
- **discontinuous precipitation**
  - Precipitation from a supersaturated solid solution in which the precipitate particles grow by short-range diffusion, accompanied by recrystallization of the matrix in the region of precipitation. Discontinuous precipitates grow into the matrix from nuclei near grain boundaries, forming cells of alternate lamellae of precipitate and depleted (and recrystallized) matrix. Often referred to as cellular or nodular precipitation. Compare with continuous precipitation , localized precipitation .
- **dissociation**
  - As applied to heterogeneous equilibria, the transformation of one phase into two or more new phases of different composition. Compare with order-disorder transformation .
- **double aging**
  - Employment of two different aging treatments to control the type of precipitate formed from a supersaturated matrix in order to obtain the desired properties. The first aging treatment, sometimes referred to as intermediate or stabilizing, is usually carried out at higher temperature than the second.
- **double tempering**
  - A treatment in which a quench-hardened ferrous metal is subjected to two complete tempering cycles, usually at substantially the same temperature, for the purpose of ensuring completion of the tempering reaction and promoting stability of the resulting microstructure.
- **drawing**
  - A misnomer for *tempering*.
- **dry cyaniding**
  - (obsolete) Same as carbonitriding .
- **ductile cast iron**
  - A cast iron that has been treated while molten with an element such as magnesium or cerium to induce the formation of free graphite as nodules or spherulites, which imparts a measurable degree of ductility to the cast metal. Also known as nodular cast iron, spherulitic graphite cast iron and SG iron.
- **ductile fracture**
  - Fracture characterized by tearing of metal accompanied by appreciable gross plastic deformation and expenditure of considerable energy. Contrast with brittle fracture .
- **ductility**
  - The ability of a material to deform plastically without fracturing, measured by elongation or reduction of area in a tensile test, by height of cupping in an Erichsen test, or by other means.
- **E**
- **885 °F (475 °C) embrittlement**
  - Embrittlement of stainless steels upon extended exposure to temperatures between 400 and 510 °F). This type of embrittlement is caused by fine, chromium-rich precipitates that segregate at grain boundaries; time at temperature directly influences the amount of segregation. Grain-boundary segregation of the chromium-rich precipitates increases strength and hardness, decreases ductility and toughness, and changes corrosion resistance. This type of embrittlement can be reversed by heating above the precipitation range.
- **elastic limit**
  - The maximum stress that a material is capable of sustaining without any permanent strain (deformation) remaining upon complete release of the stress.
- **electron-beam heat treating**
  - A selective surface hardening process that rapidly heats a surface by direct bombardment with an accelerated stream of electrons.
- **embrittlement**

- The severe loss of ductility or toughness or both, of a material, usually a metal or alloy. Many forms of embrittlement can lead to brittle fracture . Many forms can occur during thermal treatment or elevated-temperature service (thermally induced embrittlement). Some of these forms of embrittlement, which affect steels, include blue brittleness , 885 °F (475 °C) embrittlement , quench-age embrittlement , sigma-phase embrittlement , strain-age embrittlement , temper embrittlement , tempered martensite embrittlement , and thermal embrittlement . In addition, steels and other metals and alloys can be embrittled by environmental conditions (environmentally assisted embrittlement). The forms of environmental embrittlement include acid embrittlement, caustic embrittlement, corrosion embrittlement, creep-rupture embrittlement, hydrogen embrittlement, liquid metal embrittlement, neutron embrittlement, solder embrittlement, solid metal embrittlement, and stress-corrosion cracking. These environmentally-related terms are defined elsewhere in this Handbook series.

- **enantiotropy**
  - The relation of crystal forms of the same substance in which one form is stable above a certain temperature and the other form stable below that temperature. Ferrite and austenite are enantiotropic in ferrous alloys, for example.
- **end-quench hardenability test**
  - A laboratory procedure for determining the hardenability of a steel or other ferrous alloy; widely referred to as the Jominy test . Hardenability is determined by heating a standard specimen above the upper critical temperature, placing the hot specimen in a fixture so that a stream of cold water impinges on one end, and, after cooling to room temperature is completed, measuring the hardness near the surface of the specimen at regularly spaced intervals along its length. The data are normally plotted as hardness versus distance from the quenched end.
- **equilibrium diagram**
  - A graphical representation of the temperature, pressure and composition limits of phase fields in an alloy system as they exist under conditions of complete equilibrium. In metal systems, pressure is usually considered constant.
- **eutectic**
  - (1) An isothermal reversible reaction in which a liquid solution is converted into two or more intimately mixed solids on cooling, the number of solids formed being the same as the number of components in the system. (2) An alloy having the composition indicated by the eutectic point on an equilibrium diagram. (3) An alloy structure of intermixed solid constituents formed by a eutectic reaction.
- **eutectic carbide**
  - Carbide formed during freezing as one of the mutually insoluble phases participating in the eutectic reaction of ferrous alloys.
- **eutectic melting**
  - Melting of localized microscopic areas whose composition corresponds to that of the eutectic in the system.
- **eutectoid**
  - (I) An isothermal reversible reaction in which a solid solution is converted into two or more intimately mixed solids on cooling, the number of solids formed being the same as the number of components in the system. (2) An alloy having the composition indicated by the eutectoid point on an equilibrium diagram. (3) An alloy structure of intermixed solid constituents formed by a eutectoid reaction.
- **extra hard**
  - A temper of nonferrous alloys and some ferrous alloys characterized by tensile strength and hardness about one-third of the way from full hard to extra spring temper.
- **extra spring**
  - A temper of nonferrous alloys and some ferrous alloys corresponding approximately to a cold-worked state above full hard beyond which further cold work will not measurably increase the strength and hardness.
- **F**
- **ferrite**
  - A solid solution of one or more elements in body-centered cubic iron. Unless otherwise designated (for instance, as chromium ferrite), the solute is generally assumed to be carbon. On some equilibrium diagrams, there are two ferrite regions separated by an austenite area. The

lower area is alpha ferrite; the upper, delta ferrite. If there is no designation, alpha ferrite is assumed.

- **ferritizing anneal**
  - A treatment given as-cast gray or ductile (nodular) iron to produce an essentially ferritic matrix. For the term to be meaningful, the final microstructure desired or the time-temperature cycle used must be specified.
- **final annealing**
  - An imprecise term used to denote the last anneal given to a nonferrous alloy prior to shipment.
- **finish annealing**
  - A subcritical annealing treatment applied to cold-worked low- or medium-carbon steel. Finish annealing, which is a compromise treatment, lowers residual stresses, thereby minimizing the risk of distortion in machining while retaining most of the benefits to machinability contributed by cold working. Compare with final annealing .
- **finishing temperature**
  - The temperature at which hot working is completed.
- **fixturing**
  - The placing of parts to be heat treated in a constraining or semiconstraining apparatus to avoid heat-related distortions. See racking .
- **flame annealing**
  - Annealing in which the heat is applied directly by a flame.
- **flame hardening**
  - A process for hardening the surfaces of hardenable ferrous alloys in which an intense flame is used to heat the surface layers above the upper transformation temperature, whereupon the workpiece is immediately quenched.
- **flame straightening**
  - Correcting distortion in metal structures by localized heating with a gas flame.
- **fluidized-bed heating**
  - Heating carried out in a medium of solid particles suspended in a flow of gas.
- **fog quenching**
  - Quenching in a fine vapor or mist.
- **forced-air quench**
  - A quench utilizing blasts of compressed air against relatively small parts such as a gear.
- **free carbon**
  - The part of the total carbon in steel or cast iron that is present in elemental form as graphite or temper carbon. Contrast with combined carbon .
- **free ferrite**
  - Ferrite that is formed directly from the decomposition of hypoeutectoid austenite during cooling, without the simultaneous formation of cementite. Also proeutectoid ferrite.
- **freezing range**
  - That temperature range between liquidus and solidus temperatures in which molten and solid constituents coexist.
- **full annealing**
  - An imprecise term that denotes an annealing cycle to produce minimum strength and hardness. For the term to be meaningful, the composition and starting condition of the material and the time-temperature cycle used must be stated.
- **full hard**
  - A temper of nonferrous alloys and some ferrous alloys corresponding approximately to a cold-worked state beyond which the material can no longer be formed by bending. In specifications, a full hard temper is commonly defined in terms of minimum hardness or minimum tensile strength (or, alternatively, a range of hardness or strength) corresponding to a specific percentage of cold reduction following a full anneal. For aluminum, a full hard temper is equivalent to a reduction of 75% from dead soft ; for austenitic stainless steels, a reduction of about 50 to 55%.
- **G**
- **gamma iron**
  - The face-centered cubic form of pure iron, stable from 910 to 1400 °C (1670 to 2550 °F).
- **gas cyaniding**
  - A misnomer for carbonitriding .
- **grain-boundary liquation**

- An advanced stage of overheating in which material in the region of austenitic grain boundaries melts. Also termed burning .
- **grain coarsening**
  - A heat treatment that produces excessively large austenitic grains.
- **grain growth**
  - An increase in the average size of the grains in polycrystalline metal, usually as a result of heating at elevated temperature.
- **grain refiner**
  - A material added to a molten metal to induce a finer-than-normal grain size in the final structure.
- **grain size**
  - For metals, a measure of the areas or volumes of grains in a polycrystalline material, usually expressed as an average when the individual sizes are fairly uniform. In metals containing two or more phases, the grain size refers to that of the matrix unless otherwise specified. Grain sizes are reported in terms of number of grains per unit area or volume, average diameter, or as a grain-size number derived from area measurements.
- **graphitic carbon**
  - Free carbon in steel or cast iron. See graphitization .
- **graphitization**
  - Formation of graphite in iron or steel. Where graphite is formed during solidification, the phenomenon is called primary graphitization; where formed later by heat treatment, secondary graphitization.
- **graphitizing**
  - Annealing a ferrous alloy in such a way that some or all of the carbon is precipitated as graphite.
- **Grossmann chart**
  - A chart describing the ability of a quenching medium to extract heat from a hot steel work-piece in comparison to still water.
- **Guinier-Preston (G-P) zone**
  - A small precipitation domain in a supersaturated metallic solid solution. A G-P zone has no well-defined crystalline structure of its own and contains an abnormally high concentration of solute atoms. The formation of G-P zones constitutes the first stage of precipitation and is usually accompanied by a change in properties of the solid solution in which they occur.
- **H**
- **half hard**
  - A temper of nonferrous alloys and some ferrous alloys characterized by tensile strength about mid-way between that of dead soft and full hard tempers.
- **hardenability**
  - The relative ability of a ferrous alloy to form martensite when quenched from a temperature above the upper critical temperature. Hardenability is commonly measured as the distance below a quenched surface where the metal exhibits a specific hardness (50 HRC, for example) or a specific percentage of martensite in the microstructure.
- **hardening**
  - Increasing hardness by suitable treatment, usually involving heating and cooling. When applicable, the following more specific terms should be used: age hardening , flame hardening , induction hardening , laser hardening , precipitation hardening , and quench hardening .
- **hardness profile**
  - Hardness as a function of distance from a fixed reference point (usually from the surface).
- **hard temper**
  - Same as full hard temper.
- **heat tinting**
  - Coloration of a metal surface through oxidation by heating to reveal details of the microstructure.
- **heat-treatable alloy**
  - An alloy that can be hardened by heat treatment.
- **heat-treating film**
  - A thin coating or film, usually an oxide, formed on the surface of metals during heat treatment.
- **heat treatment**
  - Heating and cooling a solid metal or alloy in such a way as to obtain desired conditions or properties. Heating for the sole purpose of hot working is excluded from the meaning of this definition.

- **holding**
  - The portion of the thermal cycle during which the temperature of the object is maintained constant.
- **holding temperature**
  - The constant temperature at which the object is maintained.
- **holding time**
  - Time for which the temperature of the object is maintained constant.
- **homogeneous carburizing**
  - Use of a carburizing process to convert a low-carbon ferrous alloy to one of uniform and higher carbon content throughout the section.
- **homogenizing**
  - Holding at high temperature to eliminate or decrease chemical segregation by diffusion.
- **horizontal batch furnace**
  - A versatile batch-type furnace that can give light or deep case depths, and because the parts are not exposed to air, horizontal batch furnaces can give surfaces almost entirely free of oxides.
- **hot quenching**
  - An imprecise term used to cover a variety of quenching procedures in which a quenching medium is maintained at a prescribed temperature above 70 °C (160 °F).
- **hot-wire analyzer**
  - An electrical atmosphere analysis device that is based on the fact that the electrical resistivity of steel is a linear function of carbon content over a range from 0.05% C to saturation. The device measures the carbon potential of furnace atmospheres (typically). This term is not to be confused with the hot-wire test which measures heat extraction rates.
- **hot-wire test**
  - Method used to test heat extraction rates of various quenchants. Faster heat-extracting quenchants will permit more electric current to pass through a standard wire because it is cooled more quickly. Compare with hot-wire analyzer .
- **hypereutectic alloy**
  - In an alloy system exhibiting a eutectic, any alloy whose composition has an excess of alloying element compared with the eutectic composition, and whose equilibrium microstructure contains some eutectic structure.
- **hypereutectoid alloy**
  - In an alloy system exhibiting a eutectoid, any alloy whose composition has an excess of alloying element compared with the eutectoid composition, and whose equilibrium microstructure contains some eutectoid structure.
- **hypoeutectic alloy**
  - In an alloy system exhibiting a eutectic, any alloy whose composition has an excess of base metal compared with the eutectic composition, and whose equilibrium microstructure contains some eutectic structure.
- **hypoeutectoid alloy**
  - In an alloy system exhibiting a eutectoid, any alloy whose composition has an excess of base metal compared with the eutectoid composition, and whose equilibrium microstructure contains some eutectoid structure.
- **I**
- **ideal critical diameter**
  - (D_I). Under an ideal quench condition, the bar diameter that has 50% martensite at the center of the bar when the surface is cooled at an infinitely rapid rate (that is, when $H = \infty$, where H is the quench severity factor).
- **immersed-electrode furnaces**
  - A furnace used for liquid carburizing of parts by heating molten salt baths with the use of electrodes immersed in the liquid. See submerged-electrode furnace .
- **impact tube**
  - Same as Pitot tube .
- **induction hardening**
  - A surface-hardening process in which only the surface layer of a suitable ferrous workpiece is heated by electromagnetic induction to above the upper critical temperature and immediately quenched.
- **induction heating**

    - Heating by combined electrical resistance and hysteresis losses induced by subjecting a metal to the varying magnetic field surrounding a coil carrying alternating current.
- **induction tempering**
    - Tempering of steel using low-frequency electrical induction heating .
- **infrared analyzer**
    - An atmosphere-monitoring device that measures a gas (usually carbon monoxide, carbon dioxide, and methane) presence based on specific wavelength absorption of infrared energy.
- **intense quenching**
    - Quenching in which the quenching medium is cooling the part at a rate at least two and a half times faster than still water. See Grossmann chart .
- **intercritical annealing**
    - Any annealing treatment that involves heating to, and holding at, a temperature between the upper and lower critical temperatures to obtain partial austenitization, followed by either slow cooling or holding at a temperature below the lower critical temperature.
- **intergranular**
    - Between crystals or grains. Also called intercrystalline. Contrast with transgranular .
- **intergranular cracking**
    - Cracking or fracturing that occurs between the grains or crystals in a polycrystalline aggregate. Also called intercrystalline cracking. Contrast with transgranular cracking .
- **intergranular fracture**
    - Brittle fracture of a metal in which the fracture is between the grains, or crystals, that form the metal. Also called intercrystalline fracture. Contrast with transgranular fracture .
- **intermediate annealing**
    - Annealing wrought metals at one or more stages during manufacture and before final treatment.
- **interrupted aging**
    - Aging at two or more temperatures, by steps, and cooling to room temperature after each step. See aging , and compare with progressive aging and step aging .
- **interrupted quenching**
    - A quenching procedure in which the workpiece is removed from the first quench at a temperature substantially higher than that of the quenchant and is then subjected to a second quenching system having a different cooling rate than the first.
- **interval test**
    - Method used to test heat extraction rates of various quenchants. This test measures the increase in temperature of a quenchant when a standard bar of metal is quenched for five seconds. Faster quenchants will exhibit greater temperature increases.
- **ion carburizing**
    - A method of surface hardening in which carbon ions are diffused into a workpiece in a vacuum through the use of high-voltage electrical energy. Synonymous with plasma carburizing or glow-discharge carburizing.
- **ion nitriding**
    - A method of surface hardening in which nitrogen ions are diffused into a workpiece in a vacuum through the use of high-voltage electrical energy. Synonymous with plasma nitriding or glow-discharge nitriding.
- **isothermal annealing**
    - Austenitizing a ferrous alloy and then cooling to and holding at a temperature at which austenite transforms to a relatively soft ferrite carbide aggregate.
- **isothermal transformation**
    - A change in phase that takes place at a constant temperature. The time required for transformation to be completed, and in some instances the time delay before transformation begins, depends on the amount of supercooling below (or superheating above) the equilibrium temperature for the same transformation.
- **isothermal transformation (IT) diagram**
    - Set of curves drawn using logarithmic time and linear temperature as coordinates, which define for each level of temperature the beginning and end of the transformation of the initial phase under isothermal conditions.
- **J**
- **Jominy test**
    - See end-quench hardenability test .

- K
- **kish**
  - Free graphite that forms in molten hypereutectic cast iron as it cools. In castings, the kish may segregate toward the cope surface, where it lodges at or immediately beneath the casting surface.
- L
- **laser hardening**
  - A surface-hardening process which uses a laser to quickly heat a surface. Heat conduction into the interior of the part will quickly cool the surface, leaving a shallow martensitic layer.
- **latent heat**
  - Thermal energy absorbed or released when a substance undergoes a phase change.
- **ledeburite**
  - The eutectic of the iron-carbon system, the constituents being austenite and cementite. The austenite decomposes into ferrite and cementite on cooling below the Ar_1.
- **Leidenfrost phenomenon**
  - Slow cooling rates associated with a hot vapor blanket that surrounds a part being quenched in a liquid medium such as water. The gaseous vapor envelope acts as an insulator, thus slowing the cooling rate.
- **liquation temperature**
  - The lowest temperature at which partial melting can occur in an alloy that exhibits the greatest possible degree of segregation.
- **liquid carburizing**
  - Surface hardening of steel by immersion into a molten bath consisting of cyanides and other salts.
- **liquid nitriding**
  - A method of surface hardening in which molten nitrogen-bearing, fused-salt baths containing both cyanides and cyanates are exposed to parts at subcritical temperatures.
- **liquid nitrocarburizing**
  - A nitrocarburizing process (where both carbon and nitrogen are absorbed into the surface) utilizing molten liquid salt baths below the lower critical temperature.
- **liquid spray quench**
  - Same as spray quenching .
- **localized precipitation**
  - Precipitation from a supersaturated solid solution similar to continuous precipitation , except that the precipitate particles form at preferred locations, such as along slip planes, grain boundaries, or incoherent twin boundaries.
- M
- **magnetic test**
  - Method used to test heat extraction rates of various quenchants. The test works by utilizing the change in magnetic properties of metals at their Curie point--the temperature above which metals lose their magnetism.
- **malleable cast iron**
  - A cast iron made by prolonged annealing of white cast iron in which decarburization or graphitization, or both, take place to eliminate some or all of the cementite. The graphite is in the form of temper carbon. If decarburization is the predominant reaction, the product will exhibit a light fracture surface, hence, "whiteheart malleable;" otherwise, the fracture surface will be dark, hence, "blackheart malleable." Ferritic malleable has a predominantly ferritic matrix; pearlitic malleable may contain pearlitic, spheroidite or tempered martensite depending on heat treatment and desired hardness.
- **malleablizing**
  - Annealing white cast iron in such a way that some or all of the combined carbon is transformed to graphite or, in some instances, part of the carbon is removed completely.
- **maraging**
  - A precipitation-hardening treatment applied to a special group of iron-base alloys to precipitate one or more intermetallic compounds in a matrix of essentially carbon-free martensite.
- **marquenching**
  - See martempering .
- **martempering**
  - (1) A hardening procedure in which an austenitized ferrous workpiece is quenched into an appropriate medium whose temperature is maintained substantially at the M_s of the workpiece,

held in the medium until its temperature is uniform throughout--but not long enough to permit bainite to form--and then cooled in air. The treatment is frequently followed by tempering. (2) When the process is applied to carburized material, the controlling M_s temperature is that of the case. This variation of the process is frequently called marquenching.

- **martensite**
  - A generic term for microstructures formed by diffusionless phase transformation in which the parent and product phases have a specific crystallographic relationship. Martensite is characterized by an acicular pattern in the microstructure in both ferrous and nonferrous alloys. In alloys where the solute atoms occupy interstitial positions in the martensitic lattice (such as carbon in iron), the structure is hard and highly strained; but where the solute atoms occupy substitutional positions (such as nickel in iron), the martensite is soft and ductile. The amount of high-temperature phase that transforms to martensite on cooling depends to a large extent on the lowest temperature attained, there being a rather distinct beginning temperature (M_s) and a temperature at which the transformation is essentially complete (M_f).
- **martensite range**
  - The temperature interval between M_s and M_f.
- **martensitic transformation**
  - A reaction that takes place in some metals on cooling, with the formation of an acicular structure called martensite .
- **McQuaid-Ehn test**
  - A test to reveal grain size after heating into the austenitic temperature range. Eight standard McQuaid-Ehn grain sizes rate the structure, No. 8 being finest, No. 1 coarsest.
- **M_f temperature**
  - For any alloy system, the temperature at which martensite formation on cooling is essentially finished. See transformation temperature for the definition applicable to ferrous alloys.
- **microhardness**
  - The hardness of a material as determined by forcing an indenter such as a Vickers or Knoop indenter into the surface of a material under very light load; usually, the indentations are so small that they must be measured with a microscope. Capable of determining hardnesses of different microconstituents within a structure, or of measuring steep hardness gradients such as those encountered in case hardening.
- **microscopic stresses**
  - Residual stresses that vary from tension to compression in a distance (presumably approximating the grain size) that is small compared with the gage length in ordinary strain measurements. They are not detectable by dissection methods, but can sometimes be measured from line shift or line broadening in an x-ray diffraction pattern.
- **microsegregation**
  - Segregation within a grain, crystal, or small particle.
- **mill scale**
  - The heavy oxide layer formed during hot fabrication or heat treatment of metals.
- **monotropism**
  - The ability of a solid to exist in two or more forms (crystal structures), but in which one form is the stable modification at all temperatures and pressures. Ferrite and martensite are a monotropic pair below Ac_1 in steels, for example. May also be spelled monotrophism.
- **M_s temperature**
  - For any alloy system, the temperature at which martensite starts to form on cooling. See transformation temperature for the definition applicable to ferrous alloys.
- **N**
- **natural aging**
  - Spontaneous aging of a supersaturated solid solution at room temperature. See aging , and compare with artificial aging .
- **neutral flame**
  - A gas flame in which there is no excess of either fuel or oxygen in the inner flame. Oxygen from ambient air is used to complete the combustion of CO_2 and H_2 produced in the inner flame.
- **neutralization number**
  - An ASTM number given to quenching oils that reflects the oil's tendency towards oxidation and sludging. See saponification number .
- **nitriding**

- Introducing nitrogen into the surface layer of a solid ferrous alloy by holding at a suitable temperature (below Ac_1 for ferritic steels) in contact with a nitrogenous material, usually ammonia or molten cyanide of appropriate composition. Quenching is not required to produce a hard case. See aerated bath nitriding , bright nitriding , and liquid nitriding .

- **nitrocarburizing**
  - Any of several processes in which both nitrogen and carbon are absorbed into the surface layers of a ferrous material at temperatures below the lower critical temperature and, by diffusion, create a concentration gradient. Nitrocarburizing is done mainly to provide an antiscuffing surface layer and to improve fatigue resistance. Compare with carbonitriding .
- **normalizing**
  - Heating a ferrous alloy to a suitable temperature above the transformation range and then cooling in air to a temperature substantially below the transformation range.
- **nucleation**
  - The initiation of a phase transformation at discrete sites, the new phase growing on nuclei. See nucleus .
- **nucleus**
  - The first structurally stable particle capable of initiating recrystallization of a phase or the growth of a new phase, and possessing an interface with the parent matrix. The term is also applied to a foreign particle that initiates such action.
- **O**
- **oil hardening**
  - Quench-hardening treatment involving cooling in oil.
- **oil quenching**
  - Hardening of carbon steel in an oil bath. Oils are categorized as conventional, fast, martempering , or hot quenching .
- **optical pyrometer**
  - An instrument for measuring the temperature of heated material by comparing the intensity of light emitted with a known intensity of an incandescent lamp filament.
- **order-disorder transformation**
  - A phase change among two solid solutions having the same crystal structure, but in which the atoms of one phase (disordered) are randomly distributed; in the other, the different kinds of atoms occur in a regular sequence upon the crystal lattice, that is, in an ordered arrangement. Compare with dissociation .
- **order hardening**
  - A low-temperature annealing treatment that permits short-range ordering of solute atoms within a matrix, which greatly impedes dislocation motion.
- **Orsat analyzer**
  - An atmosphere analysis device in which gases are absorbed selectively (volumetric basis) by passing them through a series of preselected solvents.
- **overaging**
  - Aging under conditions of time and temperature greater than those required to obtain maximum change in a certain property, so that the property is altered in the direction of the initial value. See aging .
- **overheating**
  - Heating a metal or alloy to such a high temperature that its properties are impaired. When the original properties cannot be restored by further heat treating, by mechanical working, or by a combination of working and heat treating, the overheating is known as burning .
- **oxidation**
  - (1) A reaction in which there is an increase in valence resulting from a loss of electrons. (2) A corrosion reaction in which the corroded metal forms an oxide; usually applied to reaction with a gas containing elemental oxygen, such as air.
- **oxidized surface (on steel)**
  - Surface having a thin, tightly adhering, oxidized skin (from straw to blue in color), extending in from the edge of a coil or sheet. Sometimes called annealing border.
- **oxidizing agent**
  - A compound that causes oxidation, thereby itself becoming reduced.
- **oxidizing flame**
  - A gas flame produced with excess oxygen in the inner flame.

- **oxygen probe**
  - An atmosphere-monitoring device that electronically measures the difference between the partial pressure of oxygen in a furnace or furnace supply atmosphere and the external air.
- **P**
- **pack carburizing**
  - A method of surface hardening of steel in which parts are packed in a steel box with the carburizing compound and heated to elevated temperatures.
- **pack nitriding**
  - A method of surface hardening of steel in which parts are packed in a steel box with the nitriding compound and heated to elevated temperatures.
- **partial annealing**
  - An imprecise term used to denote a treatment given cold-worked material to reduce the strength to a controlled level or to effect stress relief. To be meaningful, the type of material, the degree of cold work, and the time-temperature schedule must be stated.
- **patenting**
  - In wiremaking, a heat treatment applied to medium-carbon or high-carbon steel before the drawing of wire or between drafts. This process consists of heating to a temperature above the transformation range and then cooling to a temperature below Ae_1 in air or in a bath of molten lead or salt.
- **pearlite**
  - A metastable lamellar aggregate of ferrite and cementite resulting from the transformation of austenite at temperatures above the bainite range.
- **phase diagram**
  - A graphical representation of the temperature and composition limits of phase fields in an alloy system as they actually exist under the specific conditions of heating or cooling (synonymous with constitution diagram). A phase diagram may be an equilibrium diagram, an approximation to an equilibrium diagram, or a representation of metastable conditions or phases. Compare with equilibrium diagram .
- **Pirani gage**
  - An instrument used to measure the pressure inside a vacuum chamber. The gage measures electrical resistance in a wire filament which will change in temperature depending on atmospheric pressure.
- **Pitot tube**
  - An instrument that measures the stagnation pressure of a flowing fluid, consisting of an open tube pointing into the fluid and connected to a pressure-indicating device. Also known as impact tube .
- **plasma carburizing**
  - Same as ion carburizing .
- **plasma nitriding**
  - Same as ion nitriding .
- **plastic deformation**
  - The permanent (inelastic) distortion of metals under applied stresses that strain the material beyond its elastic limit .
- **polymorphism**
  - The property of a chemical substance crystallizing into two or more forms having different structures, such as diamond and graphite.
- **postheating**
  - Heating weldments immediately after welding, for tempering, for stress relieving, or for providing a controlled rate of cooling to prevent formation of a hard or brittle structure.
- **pot annealing**
  - Same as box annealing .
- **precipitation hardening**
  - Hardening caused by the precipitation of a constituent from a supersaturated solid solution. See also age hardening and aging .
- **precipitation heat treatment**
  - Artificial aging in which a constituent precipitates from a supersaturated solid solution.
- **preheating**
  - Heating before some further thermal or mechanical treatment. For tool steel, heating to an intermediate temperature immediately before final austenitizing. For some nonferrous alloys,

heating to a high temperature for a long time, to homogenize the structure before working. In welding and related processes, heating to an intermediate temperature for a short time immediately before welding, brazing, soldering, cutting, or thermal spraying.

- **press quenching**
  - A quench in which hot dies are pressed and aligned with a part before the quenching process begins. Then the part is placed in contact with a quenching medium in a controlled manner. This process avoids part distortion.
- **process annealing**
  - An imprecise term denoting various treatments used to improve workability. For the term to be meaningful, the condition of the material and the time-temperature cycle used must be stated.
- **progressive aging**
  - Aging by increasing the temperature in steps or continuously during the aging cycle. See aging and compare with interrupted aging and step aging.
- **pseudocarburizing**
  - See blank carburizing .
- **pseudonitriding**
  - See blank nitriding .
- **pusher furnace**
  - A type of continuous furnace in which parts to be heated are periodically charged into the furnace in containers, which are pushed along the hearth against a line of previously charged containers thus advancing the containers toward the discharge end of the furnace, where they are removed.
- **pyrometer**
  - A device for measuring temperatures above the range of liquid thermometers.
- **Q**
- **quarter hard**
  - A temper of nonferrous alloys and some ferrous alloys characterized by tensile strength about midway between that of dead soft and half hard tempers.
- **quench-age embrittlement**
  - Embrittlement of low-carbon steels resulting from precipitation of solute carbon at existing dislocations and from precipitation hardening of the steel caused by differences in ferrite at different temperatures. Quenchage embrittlement usually is caused by rapid cooling of the steel from temperatures slightly below Ac_1 (the temperature at which austenite begins to form), and can be minimized by quenching from lower temperatures.
- **quench aging**
  - Aging induced by rapid cooling after solution heat treatment .
- **quench annealing**
  - Annealing an austenitic ferrous alloy by solution heat treatment followed by rapid quenching.
- **quench cracking**
  - Fracture of a metal during quenching from elevated temperature. Most frequently observed in hardened carbon steel, alloy steel, or tool steel parts of high hardness and low toughness. Cracks often emanate from fillets, holes, corners, or other stress raisers and result from high stresses due to the volume changes accompanying transformation to martensite.
- **quench hardening**
  - (1) Hardening suitable alpha-beta alloys (most often certain copper to titanium alloys) by solution treating and quenching to develop a martensitic-like structure. (2) In ferrous alloys, hardening by austenitizing and then cooling at a rate such that a substantial amount of austenite transforms to martensite.
- **quenching**
  - Rapid cooling. When applicable, the following more specific terms should be used: brine quenching , caustic quenching , cold die quenching , forced-air quenching , intense quenching , oil quenching , press quenching , spray quenching , direct quenching , fog quenching , hot quenching , interrupted quenching , selective quenching , time quenching , and water quenching .
- **R**
- **racking**
  - A term used to describe the placing of parts to be heat treated on a rack or tray. This is done to keep pans in a proper position to avoid heat-related distortions and to keep the parts separated. See fixturing .
- **recalescence**

- A phenomenon, associated with the transformation of gamma iron to alpha iron on the cooling (supercooling) of iron or steel, revealed by the brightening (reglowing) of the metal surface owing to the sudden increase in temperature caused by the fast liberation of the latent heat of transformation. Contrast with decalescence .

- **recarburize**
    - (1) To increase the carbon content of molten cast iron or steel by adding carbonaceous material, high-carbon pig iron, or a high-carbon alloy. (2) To carburize a metal part to return surface carbon lost in processing; also known as carbon restoration.
- **recovery**
    - Reduction or removal of work-hardening effects, without motion of large-angle grain boundaries.
- **recrystallization**
    - (1) The formation of a new, strain-free grain structure from that existing in cold-worked metal, usually accomplished by heating. (2) The change from one crystal structure to another, as occurs on heating or cooling through a critical temperature.
- **recrystallization annealing**
    - Annealing cold-worked metal to produce a new grain structure without phase change.
- **recrystallization temperature**
    - The approximate minimum temperature at which complete recrystallization of a cold-worked metal occurs within a specified time.
- **recuperator**
    - Equipment for transferring heat from gaseous products of combustion to incoming air or fuel. The incoming material passes through pipes surrounded by a chamber through which the outgoing gases pass.
- **reducing flame**
    - A gas flame produced with excess fuel in the inner flame.
- **refractory**
    - (1) A material of very high melting point with properties that make it suitable for such uses as furnace linings and kiln construction. (2) The quality of resisting heat.
- **regenerator**
    - Same as recuperator except the gaseous products of combustion heat brick checkerwork in a chamber connected to the exhaust side of the furnace while the incoming air and fuel are being heated by the brick checkerwork in a second chamber, connected to the entrance side. At intervals, the gas flow is reversed so that incoming air and fuel contact hot checker-work while that in the second chamber is being reheated by exhaust gases.
- **residual stress**
    - An internal stress not depending on external forces resulting from such factors as cold working, phase changes, or temperature gradients.
- **retort**
    - A vessel used for distillation of volatile materials, as in separation of some metals and in destructive distillation of coal.
- **reverberatory furnace**
    - A furnace with a shallow hearth, usually nonregenerative, having a roof that deflects the flame and radiates heat toward the hearth or the surface of the charge.
- **Rockwell hardness test**
    - An indentation hardness test based on the depth of penetration of a specified penetrator into the specimen under certain arbitrarily fixed conditions.
- **rotary retort furnace**
    - A continuous-type furnace in which the work advances by means of an internal spiral, which gives good control of the retention time within the heated chamber.
- **S**
- **salt bath heat treatment**
    - Heat treatment carried out in a bath of molten salt.
- **saponification number**
    - A number given to quenching oils that reflects the oils amount of compounding with fatty materials, which thereby helps evaluate the condition of these oils in service. See neutralization number .
- **selective heating**
    - Intentionally heating only certain portions of a workpiece.

- **selective quenching**
  - Quenching only certain portions of an object.
- **self-hardening steel**
  - See preferred term, air-hardening steel .
- **sensitization**
  - In austenitic stainless steels, the precipitation of chromium carbides, usually at grain boundaries, on exposure to temperatures of about 540 °C to 845 °C (about 1000 to 1550 °F), leaving the grain boundaries depleted of chromium and therefore susceptible to preferential attack by a corroding (oxidizing) medium.
- **severity of quench**
  - Ability of quenching medium to extract heat from a hot steel workpiece; expressed in terms of the *H* value.
- **shaker-hearth furnace**
  - A continuous type furnace that uses a reciprocating shaker motion to move the parts along the hearth.
- **shell hardening**
  - A surface-hardening process in which a suitable steel workpiece, when heated through and quench hardened, develops a martensitic layer or shell that closely follows the contour of the piece and surrounds a core of essentially pearlitic transformation product. This result is accomplished by a proper balance among section size, steel hardenability, and severity of quench.
- **shim**
  - A thin piece of material placed between two surfaces to obtain a proper fit, adjustment, or alignment. The piece can also be analyzed to measure furnace carbon potential (that is, because while in the furnace it will quickly carburize to a level equal to the furnace carbon potential).
- **sigma phase**
  - A hard, brittle, nonmagnetic intermediate phase with a tetragonal crystal structure, containing 30 atoms per unit cell, space group $P4_2/mnm$, occurring in many binary and ternary alloys of the transition elements. The composition of this phase in the various systems is not the same, and the phase usually exhibits a wide range in homogeneity. Alloying with a third transition element usually enlarges the field of homogeneity and extends it deep into the ternary section.
- **sigma-phase embrittlement**
  - Embrittlement of iron-chromium alloys (most notably austenitic stainless steels) caused by precipitation at grain boundaries of the hard, brittle intermetallic sigma phase during long periods of exposure to temperatures between approximately 565 and 980 °C (1050 and 1800 °F). Sigma-phase embrittlement results in severe loss in toughness and ductility and can make the embrittled material structure susceptible to intergranular corrosion. See also sensitization .
- **signal-to-noise ratio**
  - Ratio of the average response to the root-mean-square variation about the average response. Ratio of variances associated with the two parts of the performance measurement.
- **siliconizing**
  - Diffusing silicon into solid metal, usually steel, at an elevated temperature.
- **sintering**
  - The bonding of adjacent surfaces in a mass of particles by molecular or atomic attraction on heating at high temperatures below the melting temperature of any constituent in the material. Sintering strengthens a powder mass and normally produces densification and, in powdered metals, recrystallization.
- **slack quenching**
  - The incomplete hardening of steel due to quenching from the austenitizing temperature at a rate slower than the critical cooling rate for the particular steel, resulting in the formation of one or more transformation products in addition to martensite.
- **slot furnace**
  - A common batch furnace where stock is charged and removed through a slot or opening.
- **snap temper**
  - A precautionary interim stress-relieving treatment applied to high-hardenability steels immediately after quenching to prevent cracking because of delay in tempering them at the prescribed higher temperature.
- **soaking**

- Prolonged holding at a selected temperature to effect homogenization of structure or composition.
- **soft temper**
  - Same as dead soft temper.
- **solution heat treatment**
  - Heating an alloy to a suitable temperature, holding at that temperature long enough to cause one or more constituents to enter into solid solution, and then cooling rapidly enough to hold these constituents in solution.
- **sorbite**
  - (obsolete) A fine mixture of ferrite and cementite produced either by regulating the rate of cooling of steel or by tempering steel after hardening. The first type is very fine pearlite difficult to resolve under the microscope; the second type is tempered martensite.
- **spalling**
  - A chipping or flaking of a surface due to any kind of improper heat treatment or material dissociation.
- **spinodal hardening**
  - See aging .
- **spheroidite**
  - An aggregate of iron or alloy carbides of essentially spherical shape dispersed throughout a matrix of ferrite.
- **spheroidizing**
  - Heating and cooling to produce a spheroidal or globular form of carbide in steel. Spheroidizing methods frequently used are:

1. Prolonged holding at a temperature just below Ae_1
2. Heating and cooling alternately between temperatures that are just above and just below Ae_1
3. Heating to a temperature above Ae_1 or Ae_3 and then cooling very slowly in the furnace or holding at a temperature just below Ae_1
4. Cooling at a suitable rate from the minimum temperature at which all carbide is dissolved, to prevent the reformation of a carbide network, and then reheating in accordance with method 1 or 2 above. (Applicable to hypereutectoid steel containing a carbide network.)

- **spinodal structure**
  - A fine homogeneous mixture of two phases that form by the growth of composition waves in a solid solution during suitable heat treatment. The phases of a spinodal structure differ in composition from each other and from the parent phase but have the same crystal structure as the parent phase.
- **spray quenching**
  - A quenching process using spray nozzles to spray water or other liquids on a part. The quench rate is controlled by the velocity and volume of liquid per unit area per unit of time of impingement.
- **spring temper**
  - A temper of nonferrous alloys and some ferrous alloys characterized by tensile strength and hardness about two-thirds of the way from full hard to extra spring temper.
- **stabilizing treatment**
  - (1) Before finishing to final dimensions, repeatedly heating a ferrous or nonferrous part to or slightly above its normal operating temperature and then cooling to room temperature to ensure dimensional stability in service. (2) Transforming retained austenite in quenched hardenable steels, usually by cold treatment . (3) Heating a solution-treated stabilized grade of austenitic stainless steel to 870 to 900 °C (1600 to 1650 °F) to precipitate all carbon as TiC, NbC, or TaC so that sensitization is avoided on subsequent exposure to elevated temperature.
- **statistical process control**
  - The application of statistical techniques for measuring and analyzing the variation in processes.
- **statistical quality control**
  - The application of statistical techniques for measuring and improving the quality of processes and products (includes statistical process control, diagnostic tools, sampling plans, and other statistical techniques).

- **Stead's brittleness**
  - A condition of brittleness that causes transcrystalline fracture in the coarse grain structure that results from prolonged annealing of thin sheets of low-carbon steel previously rolled at a temperature below about 705 °C (1300 °F). The fracture usually occurs at about 45° to the direction of rolling.
- **step aging**
  - Aging at two or more temperatures, by steps, without cooling to room temperature after each step. See aging , and compare with interrupted aging and progressive aging .
- **strain-age embrittlement**
  - A loss in ductility accompanied by an increase in hardness and strength that occurs when low-carbon steel (especially rimmed or capped steel) is aged following plastic deformation. The degree of embrittlement is a function of aging time and temperature, occurring in a matter of minutes at about 200 °C (400 °F) but requiring a few hours to a year at room temperature.
- **strain aging**
  - Aging following plastic deformation.
- **stress equalizing**
  - A low-temperature heat treatment used to balance stresses in cold-worked material without an appreciable decrease in the mechanical strength produced by cold working.
- **stress relieving**
  - Heating to a suitable temperature, holding long enough to reduce residual stresses, and then cooling slowly enough to minimize the development of new residual stresses.
- **subcritical annealing**
  - A process anneal performed on ferrous alloys at a temperature below Ac_1.
- **submerged-electrode furnace**
  - A furnace used for liquid carburizing of parts by heating molten salt baths with the use of electrodes submerged in the ceramic lining. See immersed-electrode furnace.
- **supercooling**
  - Cooling below the temperature at which an equilibrium phase transformation can take place, without actually obtaining the transformation.
- **superheating**
  - Heating above the temperature at which an equilibrium phase transformation should occur without actually obtaining the transformation.
- **surface hardening**
  - A generic term covering several processes applicable to a suitable ferrous alloy that produces, by quench hardening only, a surface layer that is harder or more wear resistant than the core. There is no significant alteration of the chemical composition of the surface layer. The processes commonly used are carbonitriding , carburizing , induction hardening , flame hardening , nitriding , and nitrocarburizing . Use of the applicable specific process name is preferred.
- **T**
- **temper**
  - (1) In heat treatment, reheating hardened steel or hardened cast iron to some temperature below the eutectoid temperature for the purpose of decreasing hardness and increasing toughness. The process also is sometimes applied to normalized steel. (2) In tool steels, temper is sometimes used, but inadvisedly, to denote the carbon content. (3) In nonferrous alloys and in some ferrous alloys (steels that cannot be hardened by heat treatment), the hardness and strength produced by mechanical or thermal treatment, or both, and characterized by a certain structure, mechanical properties, or reduction in area during cold working.
- **temper carbon**
  - Same as annealing carbon .
- **temper color**
  - A thin, tightly adhering oxide skin that forms when steel is tempered at a low temperature, or for a short time, in air or a mildly oxidizing atmosphere. The color, which ranges from straw to blue depending on the thickness of the oxide skin, varies with both tempering time and temperature.
- **tempered martensite embrittlement**
  - Embrittlement of ultrahigh-strength steels caused by tempering in the temperature range of 205 to 400 °C (400 to 750 °F); also called 350 °C or 500 °F embrittlement. Tempered martensite embrittlement is thought to result from the combined effects of cementite precipitation on prior-

austenite grain boundaries or interlath boundaries and the segregation of impurities at prior-austenite grain boundaries.

- **temper embrittlement**
  - Embrittlement of alloy steels caused by holding within or cooling slowly through a temperature range just below the transformation range. Embrittlement is the result of the segregation at grain boundaries of impurities such as arsenic, antimony, phosphorus, and tin; it is usually manifested as an upward shift in ductile-to-brittle transition temperature. Temper embrittlement can be reversed by retempering above the critical temperature range, then cooling rapidly.
- **thermal analysis**
  - A method for determining transformations in a metal by noting the temperatures at which thermal arrests occur. These arrests are manifested by changes in slope of the plotted or mechanically traced heating and cooling curves. When such data are secured under nearly equilibrium conditions of heating and cooling, the method is commonly used for determining certain critical temperatures required for the construction of equilibrium diagrams.
- **thermal electromotive force**
  - The electromotive force generated in a circuit containing two dissimilar metals when one junction is at a temperature different from that of the other. See also thermocouple .
- **thermal fatigue**
  - Fracture resulting from the presence of temperature gradients that vary with time in such a manner as to produce cyclic stresses in a structure.
- **thermal shock**
  - The development of a steep temperature gradient and accompanying high stresses within a structure.
- **thermal stresses**
  - Stresses in metal resulting from nonuniform temperature distribution.
- **thermochemical treatment**
  - Heat treatment carried out in a medium suitably chosen to produce a change in the chemical composition of the object by exchange with the medium.
- **thermocouple**
  - A device for measuring temperatures, consisting of lengths of two dissimilar metals or alloys that are electrically joined at one end and connected to a voltage-measuring instrument at the other end. When one junction is hotter than the other, a thermal electromotive force is produced that is roughly proportional to the difference in temperature between the hot and cold junctions.
- **thermomechanical working**
  - A general term covering a variety of processes combining controlled thermal and deformation treatments to obtain specific properties. Same as thermal-mechanical treatment.
- **three-quarters hard**
  - A temper of nonferrous alloys and some ferrous alloys characterized by tensile strength and hardness about midway between those of half hard and full hard tempers.
- **time quenching**
  - A term used to describe a quench in which the cooling rate of the part being quenched must be changed abruptly at some time during the cooling cycle.
- **time-temperature-transformation (TTT) diagram**
  - See isothermal transformation (IT) diagram.
- **total carbon**
  - The sum of the free and combined carbon (including carbon in solution) in a ferrous alloy.
- **total indicator reading**
  - See preferred term total indicator variation .
- **total indicator variation**
  - The difference between the maximum and minimum indicator readings during a checking cycle.
- **toughness**
  - The ability of a metal to absorb energy and deform plastically before fracturing.
- **transcrystalline**
  - See transgranular .
- **transformation hardening**
  - Heat treatment comprising austenitization followed by cooling under conditions such that the austenite transforms more or less completely into martensite and possibly into bainite.
- **transformation-induced plasticity**

- A phenomenon, occurring chiefly in certain highly alloyed steels that have been heat treated to produce metastable austenite or metastable austenite plus martensite, whereby, on subsequent deformation, part of the austenite undergoes strain-induced transformation to martensite. Steels capable of transforming in this manner, commonly referred to as TRIP steels, are highly plastic after heat treatment, but exhibit a very high rate of strain hardening and thus have high tensile and yield strengths after plastic deformation at temperatures between about 20 and 500 °C (70 and 930 °F). Cooling to -195 °C (-320 °F) may or may not be required to complete the transformation to martensite. Tempering usually is done following transformation.

- **transformation ranges**
  - Those ranges of temperature within which a phase forms during heating and transforms during cooling. The two ranges are distinct, sometimes overlapping but never coinciding. The limiting temperatures of the ranges depend on the composition of the alloy and on the rate of change of temperature, particularly during cooling. See transformation temperature .
- **transformation temperature**
  - The temperature at which a change in phase occurs. The term is sometimes used to denote the limiting temperature of a transformation range. The following symbols are used for iron and steels.
- **Ac_{cm}**
  - In hypereutectoid steel, the temperature at which the solution of cementite in austenite is completed during heating.
- **Ac_1**
  - The temperature at which austenite begins to form during heating.
- **Ac_3**
  - The temperature at which transformation of ferrite to austenite is completed during heating.
- **Ac_4**
  - The temperature at which austenite transforms to delta ferrite during heating.
- **Ae_{cm}, Ae_1, Ae_3, Ae_4**
  - The temperatures of phase changes at equilibrium.
- **Ar_{cm}**
  - In hypereutectoid steel, the temperature at which precipitation of cementite starts during cooling.
- **Ar_1**
  - The temperature at which transformation of austenite to ferrite or to ferrite plus cementite is completed during cooling.
- **Ar_3**
  - The temperature at which austenite begins to transform to ferrite during cooling.
- **Ar_4**
  - The temperature at which delta ferrite transforms to austenite during cooling.
- **Ar'**
  - The temperature at which transformation of austenite to pearlite starts during cooling.
- **M_f**
  - The temperature at which transformation of austenite to martensite finishes during cooling.
- **M_s, (or Ar'')**
  - The temperature at which transformation of austenite to martensite starts during cooling.

    Note: All these changes except the formation of martensite occur at lower temperatures during cooling than during heating, and depend on the rate of change of temperature.

- **transgranular**
  - Through or across crystals or grains. Also called intracrystalline or transcrystalline.
- **transgranular cracking**
  - Cracking or fracturing that occurs through or across a crystal or grain. Also called transcrystalline cracking. Contrast with intergranular cracking .
- **transgranular fracture**
  - Fracture through or across the crystals or grains of a metal. Also called transcrystalline fracture or intracrystalline fracture. Contrast with intergranular fracture .
- **transition temperature**

- (1) An arbitrarily defined temperature that lies within the temperature range in which metal fracture characteristics (as usually determined by tests of notched specimens) change rapidly, such as from primarily fibrous (shear) to primarily crystalline (cleavage) fracture. Commonly used definitions are "transition temperature for 50% cleavage fracture," "10 ft · lbf transition temperature," and "transition temperature for half maximum energy." (2) Sometimes used to denote an arbitrarily defined temperature within a range in which the ductility changes rapidly with temperature.
- **TRIP steel**
  - A commercial steel product exhibiting transformation-induced plasticity .
- **troostite**
  - (obsolete) A previously unresolvable rapidly etching fine aggregate of carbide and ferrite produced either by tempering martensite at low temperature or by quenching a steel at a rate slower than the critical cooling rate. Preferred terminology for the first product is tempered martensite; for the latter, fine pearlite.
- **U**
- **undercooling**
  - Same as supercooling .
- **V**
- **vacuum annealing**
  - Annealing carried out at subatmospheric pressure.
- **vacuum carburizing**
  - A high-temperature gas carburizing process using furnace pressures between 7 and 55 kPa during the carburizing portion of the cycle.
- **vacuum furnace**
  - A furnace using low atmospheric pressures instead of a protective gas atmosphere like most heat-treating furnaces. Vacuum furnaces are categorized as hot wall or cold wall, depending on the location of the heating and insulating components.
- **vacuum nitrocarburizing**
  - A subatmospheric nitrocarburizing process using a basic atmosphere of 50% ammonia/50% methane, containing controlled oxygen additions of up to 2%.
- **W**
- **walking-beam furnace**
  - A continuous-type furnace consisting of two sets of rails, one stationary and the other movable. Only the work being processed has to be heated because trays or fixtures are not needed.
- **water quenching**
  - A quench in which water is the quenching medium. The major disadvantage of water quenching is its poor efficiency at the beginning or hot stage of the quenching process.
- **white layer**
  - Compound layer that forms as a result of the nitriding process.

Abbreviations, Symbols, and Tradenames

- **Abbreviations and Symbols**
- **a**
  - crack length; edge length in crystal structure
- **a_C**
  - activity of carbon
- **a_N**
  - activity of nitrogen
- **a_O**
  - activity of oxygen
- **A**
  - austenite; ampere; air
